

This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

- + *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.
- + *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.
- + *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.
- + *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at <http://books.google.com/>

THE
BRITISH CYCLOPÆDIA.
NATURAL HISTORY.

JACARANDA (Jussieu). A genus of tropical trees belonging to the natural order *Bignoniaceæ*. Generic character: calyx bell-shaped, five-toothed; corolla funnel-shaped, limb five-cleft spreading; stamens, anthers two-celled, rudiments of five filaments; style with a two-plated stigma; capsule roundish, compressed, woody, and two-celled; seeds in a double series, with membranous wings. This plant flowers freely in our stoves, potted in any kind of light soil; and it should be kept very dry in winter to cause it to flower more readily. Young plants may be raised from cuttings. The full sized tree forms a beautiful kind of rose-wood. The jacaranda of commerce is said to be the timber of a Brazilian mimosa.

JACQUINIA (Linnæus). A genus of tropical trees and shrubs belonging to the fifth class of Linnæus, and to the natural order *Myrsinææ*. Generic character: calyx five-cleft, persisting; corolla somewhat bell-shaped, limb ten-lobed, in two series, the lobes of the inner one smallest; stamens fixed in the base of the corolla; anthers behind; style short, bearing an obtuse stigma; berry globular and five-seeded; albumen fleshy. The jacquinias are beautiful plants, and thrive in loam mixed with moor-earth. They may be increased by cuttings, but require much care.

JALAP is a medicinal juice extracted from the *Ipomœa jalapa*, a South American plant nearly allied to *Convolvulus*. The *Mirabilis jalapa*, a species of the marvel of Peru, is also known by this name.

JAMBOSA (Decandolle). A genus of fruit trees natives of India, formerly called *Eugenia jambos*, and belonging to the beautiful order *Myrtaceæ*. This plant, with many of its near alliances, have long been cultivated in our stoves, and grow readily in good loam and moor-earth. They are readily propagated by cuttings in moist heat, or placed under a small bell-glass.

JANIPHA (Kunth). A genus of useful shrubs natives of South America, belonging to the natural order *Euphorbiaceæ*. It has been separated from the genus *Jatropha* of Linnæus.

JASMINEÆ. A small natural order containing only two genera, of which there are already described forty-two species. They are elegant and generally fragrant shrubs. From their flowers, some of the most delicious perfumes are extracted, such as the essential oil of jasmin which is distilled from the flowers of *J. grandiflorum*, *officinale*, and *odoratissimum*, as well as from the *Jasminum*, or, as it is now called, *Mogorium sambac*, which is the *Ysmyn* of the Arabs, whence our common European name. The

flowers of *M. undulatum* and *trifoliatum* are also sweet, scented; and their leaves, which have a bitter taste have been recommended as slightly stomachic, and agreeable cephalic medicines. The powdered root of *J. angustifolium* is extremely bitter, and it is said by Ainslie to be an effectual application to ringworms. *Nyctanthes arbor tristis* has likewise a very fragrant blossom, and to its expanding only towards night, and diffusing its odours chiefly during the dark, its generic and specific names allude.

Of the jasmine there are above thirty species; and of the *Officinale* there are several varieties, two of them with variegated leaves. These variegated ones present a curious physiological circumstance, which is, if a common green one be budded with a variegated sort, not only will the future head rising from the bud be variegated, but the suckers also which rise from the root.

JASPER. There are five varieties of this mineral commonly found in the cabinets of collectors. Egyptian jasper, striped jasper, porcelain jasper, common jasper, and agate jasper. The first kind is found in several parts of Africa, and whatever may have been its original formation, it is now frequently discovered in detached masses embedded in sand.

There are some fine specimens of the second kind in the Pentland Hills, near Edinburgh, and also in Germany, which is also the case with the remaining varieties; but the last is more generally found in the agates of the Lothians.

The jaspers vary considerably in their colour, and also in their value, as the latter depends very much on the beauty of their tints. The red Egyptian jasper frequently passes into flint, from which, however, it may be distinguished by its opacity and inferior degree of hardness. Some of the largest and most beautiful snuff-boxes are formed of this mineral; so that it is common in Egypt for the political expectants of the Pacha to calculate the value of an appointment by the size of the jasper box, which are its first fruits. There are some very fine specimens of jasper in the mineralogical gallery of the British Museum.

JATROPHA (Linnæus). Tropical shrubs, commonly called the physic-nut tree in the West Indies. The genus belongs to *Euphorbiaceæ*, and some of the species now called *Janipha* are important both as medicine and food. The physic-nuts are the seeds of the *J. curcas*, but those of *multifida* are cathartic likewise. One species, *J. manihot*, affords the celebrated manioc of the negroes; known, however, better by the name of cassava in the West Indies, and tapioca of Brazil.

This very mild, innoxious, and nutritious food, is remarkable for being the produce of the root of the *Manihot*, which, when in its fresh state, is highly poisonous; the juice with which it abounds would form a deadly draught, and is even used by the savages to envenom their spears and darts. The deleterious principle is very volatile, passing off from the roots after they have been kept for thirty-six hours, and is immediately dissipated by heat. Two ounces of cassava will suffice for a meal, and a pound will support a man for twenty-four hours.

JERUSALEM ARTICHOKE is the *Helianthus tuberosus* of Linnæus, a well known culinary plant. They are cultivated in the manner of potatoes, but usually in some out of the way part of the garden, as they grow tall, and when once planted are difficult to eradicate.

JIGGER. See CHIGOE.

JONQUIL is the *Narcissus jonquilla* of Linnæus, one of the sweetest and most elegant of its family.

JUGLANDEÆ. A small natural order of trees comprising only two genera, viz., *Juglans* and *Carya*—the walnut and the hickory nut. Their flowers are monœcious; those bearing stamens are collected into aments or catkins, and the pistilline flowers are single, or in twos or threes together on short footstalks. The fruit is drupaceous, globular, or sub-ovate. The embryo is large, with two wrinkled, oily, and fleshy cotyledons, the radicle short and superior, and the plumula with two pennate leaves.

The *Juglandææ* are much esteemed both for their timber and fruit. Before the introduction of mahogany and other modern fancy woods, the walnut was much prized and greatly employed in the construction of ornamental furniture; its chief use now is for gun-stocks, and during the late war fetched a high price.

The fleshy cotyledons of the nuts abound in oil, which is in some places expressed. It is one of the oils which do not congeal by cold, and which, drying on exposure to the air, are valuable in the art of painting. It is also used instead of olive and almond oils in cookery. The *mark* or *nut-bread*, as it is called, which is left after the expression of the oil, is very nutritious, and is used to fatten poultry and other domestic animals.

An opinion has long prevailed that the exhalations of the common walnut-tree are deleterious, producing stupor, &c., in those who sit under its shade. These accounts are, doubtless, exaggerated; but it is well known that the strong odour of the leaves produces headache in many persons.

The different species of hickory yield nuts less grateful than the true walnuts, but still wholesome and nutritious. The best are those of the *Carya olivæformis* and *sulcata*; the first named is the Pekea nut, and its flavour is delicious. The bark of *C. alba* is acrid, and used as a caustic; its wood is of a light colour, and valuable for its elasticity and toughness.

JULUS (Linnæus). A genus of apterous insects belonging to the order *Chilognatha* of MacLeay, and to the class *Myriapoda* of Latreille. The body is very long and cylindric, and the insects, when disturbed, roll themselves into a spiral coil. For further details relative to these insects, see the article *CHILOGNATHA*; and for an account of the imperfect species of metamorphoses which they undergo, see the article *INSECT*, where the common English species, *Julus terrestris*, is figured at three periods of its existence.

JUNCAGINEÆ. A small natural order of insignificant bog plants containing only two genera; viz. *Scheuchzeria* and *Triglochin*. These plants are not floaters, but grow more like rushes; their exalbuminous seeds, however, easily distinguish them from the *Juncææ*. They are all innoxious, but none of them have been applied to any useful purpose; they contain very little nutritious matter, and form poor fodder, which but few animals will eat.

JUNCEÆ. A small natural order comprising some of the lowest grades of vascular plants. They are generally herbaceous, rarely suffruticose; the underground stems or rhizomata are scaly, with long subterranean divisions. Hence they are often planted to strengthen sea and river walls, and various embankments. In Holland the *Juncus acutus* and *J. maritimus* vie with the mat-grasses and sand-sedges in protecting the low lands from the encroachments of the sea, by the strength their long interlacing roots give to the soil. The *Juncinææ* are none of them poisonous plants, but they are now applied to few domestic purposes, save the making mats, chair-bottoms, and brooms; their chief occupation being gone, since the advance of luxury has spread the apartments of our citizens with carpets, although, as late as the time of the last Henry, the king's chamber was only strewn with rushes, and one of the charges against cardinal Wolsey for extravagance was having his room restrewn so often as once a week.

JUNIPERUS (Linnæus). A genus of hardy trees and shrubs, chiefly natives of the northern parts of the world. The flowers are diœcious, and the genus belongs to the extensive order *Coniferææ*. The *J. excelsa* is a timber tree in Siberia; and so are those indigenous to Bermuda, Barbadoes, and Virginia. Many are only low bushes, as the common British one which covers large tracts of waste ground. The wood of the juniper is hard and durable, and its bark may be twisted into cables; but the chief use of the plant is to flavour ardent spirits. Hollands owe their taste to the berries of the juniper, and English gin is commonly believed to be flavoured with them also; but it is generally unconscious of their presence, the British manufacturers of that "cordial" poison being mostly content with the substitution of oil of turpentine! Juniper berries are stimulating and diuretic, their properties depending on an essential oil which they contain. From six to eight hundred tons are annually imported into this country, but the oppressive duty to which they are subject, full 100 per cent., limits their consumption.

JUSSIEUA (Linnæus). A genus of water-plants, mostly biennials, belonging to the natural order *Onagraricææ*. Generic order: calyx tubular, somewhat three-sided, the limb of four persisting divisions; petals inserted into the calyx, and spreading, commonly four, though sometimes five or six; stamens eight, nine, or ten filaments inserted into the calyx short, anthers oval and erect; style cylindrical; stigma peltate; seed-vessel four-celled, four-valved, and many seeded; seeds naked, smooth, and minute. Some of the species are kept in our aquariums, and propagated by seeds.

KÄMPFERIA (Linnæus). A genus of East Indian herbs, having thick tuberous roots. The plants belong to the first class of Linnæus, and to the order *Scitamineææ*. The *K. galanga* is cultivated in India for its roots, which are used as an ingredient in currie,

but chiefly as a dye-stuff. They are managed in the stove by growing them in light sandy loam, sparingly watered when dormant, but plentifully when in growth: and are propagated by division.

KALMIA (Linnaeus). A genus of beautiful North American plants belonging to the tenth class of sexual botany, and to the natural order *Rhodoraceae*. The handsome figure of the shrub, the beauty of its foliage, and the exquisite form and delicate tints of the flowers, introduces these shrubs among the choicest ornaments of the flower garden. They are always grown in moor earth along with rhododendrons and the like, and as they ripen seeds plentifully, they are easily propagated.

KANGUROO (*Kangurus*). A genus of marsupial mammalia, peculiar to Australia; and in some respects one of the most extraordinary productions of the animal kingdom. They are so, from the fact of being the largest animals having a double gestation, the first uterine or internal, and performed through the medium of a placenta, and the second marsupial, or carried on in a pouch or appendage to the abdomen of the female, without the intervention of any thing like a regular placenta, unless it is considered that the teat to which the young is for some time attached, though it afterwards can attach and detach itself at pleasure, and even quit the pouch in order to browse the grass, may perhaps be considered as performing a similar office to that of a placenta, at least for some part of the period during which the young one inhabits the pouch. That there is a closer connexion between the teat of the marsupial animal and the young one which is to be nursed upon that teat, than there is between the teats of ordinary mammalia and the young which they nourish, is a point which must be admitted; for the individual teat which nurses the young one is a temporary part; and so perhaps, at least in many of the species, is the glandular apparatus, by which the nourishment of the young one is secreted. This point is indeed an obscure one; for up to a period comparatively very recent, we know little or nothing of the curious physiology of marsupial animals; and there was a strong, perhaps a too strong, disposition to consider the whole gestation of the animals as uterine, and the abdominal pouch as little else than a simple sack in which the young were carried about. Now, that the young are, in many of the species, carried in the pouch is perfectly true; but it is equally true, that the pouch performs other and far more important functions in their economy; and as there is perhaps no species in which the pouch, with all its apparatus, is more perfect than in the kangaroo, and as that animal, from its size and habits, and its ability to bear the climate of Europe, is the best subject by the observation of which to work out the general truths, it is desirable that as much attention should be paid to it as possible.

We know from actual observation, conducted at the London Zoological Gardens, under circumstances the most favourable and by parties the most competent, what portion of the whole time of development of the *fœtus*, from the pairing to the time that it is able to shift for itself, is uterine, and what part is marsupial. We know also that, preparatory to the lodgment of the embryo (for it is still very rudimental or unformed), and also for some time after it has been lodged there, there is an action of the marsupium, which, though we cannot say that it is similar

to the action of a conceiving uterus, yet bears no inconsiderable resemblance to it in many respects; and one of the most remarkable of these is the production of the teat to which the young one is to adhere.

What may be the purpose in the economy of those animals which is answered by this very extraordinary kind of gestation, we are not in a condition for determining; for all our speculations respecting the adaptation of the structure and physiology of animals to their habits and nature, and the part which they are to perform, and the purpose which they are to answer by them, have been so framed, and are still so worked out, exclusively from the examples of the placental mammalia, that they fail us whenever we attempt to give a reason for the very different formation and functions of these most extraordinary creatures.

The kangaroos are interesting in another point of view, besides this singular mode of production, which they possess, in great part at least, in common with all the marsupial animals. They are the only animals, of any considerable size, in Australia, which bear the least analogy to the ruminantia, or grazing animals of other parts of the world; and though this analogy is an exceedingly loose one, inasmuch as it applies only to the kind of food, but not to the furnishing of the mouth, by which that food is taken, or to the stomach, in which it is digested. If in these respects we consider the kangaroos, the common mammalia to which they have the nearest relation are the rodentia, or gnawing animals; and in the case of them, the analogy is also very partial, so much so indeed, that, in order to express it correctly, we ought to take it upon the negative statement, and say that the kangaroos are less unlike the rodentia than most of the other mammalia; but this is a species of saying which is calculated to convey very little information; and in the present state of our knowledge we must be contented with little more than a simple description of these animals, leaving their relations to the rest of the animal creation, and to the physical circumstances of that portion of the globe in which alone they are to be found, to be more fully illustrated when further observation shall have furnished the means.

The name kangaroo is that given to the animal by at least some of the many hordes or packs of savage inhabitants which were found in Australia at the time when it was first visited by Europeans; and probably the retaining of this name, both as the common English and the scientific one, is the wisest plan which can be adopted. That disposition to call names, by which systematic naturalists are often too much beset, has led to the application of one or two to the animals of this genus. The late Dr. Shaw, who was very laborious in compilations respecting the natural history of animals, though perhaps far from the most philosophic and discriminating that ever undertook such a task, applied the name *Macropus*, or large foot, and that name is accordingly to be met with in many of the books. Others have given different names descriptive of various parts of the structure or action of the animal; but there is none of them that reaches the real character; so that there does not appear to be any necessity for changing the native name, which, if it has no other advantage, at least possesses this one—that it does not mix up the subject for which it stands with any other genus of animals.

Altogether the kangaroos are animals of singular

appearance; and when one contrasts the anterior and the posterior parts of the body, it seems singular that they should belong to the same animal, the former are so slight and slender as compared with the latter. We have, no doubt, approaches to this in some other animals, and it is worthy of remark that those approaches are found in the rodentia, such as the hare and the jerboa; and we have mentioned that the rodentia are the least different from kangaroos of all the common mammalia. When we have stated this, however, our parallel is at an end, and we must content ourselves with noticing kangaroos as a separate genus, which cannot be explained, or the peculiarities of its structure accounted for, upon any principle of connexion.

In brief, the generic characters may be stated as follows: six incisive teeth in the upper jaw, and two in the under; five cheek teeth in each side of both jaws, but no canines in either. The head long and slender; the ears of large size and pointed; and the eyes also large. The fore legs very short, furnished with five toes on each, and armed with large claws. The hind legs very long and strong, both in their bones and their muscles; the hind feet furnished with four toes upon each; but the two inner ones are very small, and united together, so as to have the appearance of only one; the outer toe of moderate size; but the middle one very large, and armed with a claw, or, more strictly speaking, a hoof of great size, firmness, and strength. The tail very strong, often very long, and capable of much and rapid motion, but not prehensile, though the animals can make use of it as a sort of third foot in their progressive motions, and especially when standing nearly upright.

There is something very remarkable in the hind foot of the kangaroo, as differing from that of every other known species of animal, whether marsupial or not. It no doubt preserves the general structure of toes much developed and divided, and furnished with pointed claws, which render the feet of most, if not all, marsupial animals a very characteristic feature; so that one who has been in the habit of paying even a moderate degree of attention to the connexion between the developments of certain parts of animals and their general physiology, would have no hesitation in deciding whether an animal were or were not marsupial by carefully inspecting its foot; for there is something slightly approaching to the foot of a bird, in at least the greater part of them. The most remarkable structural feature of the kangaroo's hind foot is the peculiar way in which the toes are developed. The external toe is not very long, but it is thick in proportion to its length; and the claw, though not very large, is firm and powerful. The two internal toes, which, as we have said, are united, form together a sort of balance to this external one. The middle one is, however, the most remarkable portion of the foot; for the bones of it extend beyond the others in a manner unknown in any other animal; they are thick and strong in proportion to their great length; and they are terminated by perhaps the most formidable claw, taken singly and without reference to the other parts, which is to be met with among the whole of the mammalia. This claw is not a nail, placed on the upper end of the member, for the mere purpose of strengthening that as a grasping instrument; it is not crooked, like the clutching claws of those carnivorous animals which use the feet in seizing their prey; it is not in any way adapted for climbing,

or for burrowing in the ground; neither is it brought habitually into action in the locomotion of the animal. Still it is one of the most powerful appendages to an animal which we meet with, and therefore analogy leads us to conclude that it has a function to perform as important as itself is powerful.

From its combining the properties of a claw and a hoof, we may suppose that this armature of the middle toe of the kangaroo performs in part the functions of both—that is, it is both an instrument of walking, and one of hostile operations; but in the latter respect it is a defensive weapon rather than an offensive one. Still, however, as it is a general habit with very many of the grazing animals to make what may be called an active defence—that is, to anticipate the attack of a supposed enemy by making a counter attack—the kangaroo is sometimes apt to use this powerful weapon in cases where no injury is done to it, or even intended. The protecting instincts of these animals, which feed exclusively upon vegetable matter, are often very singular and apparently inexplicable; and when an enemy appears, they very frequently attack that enemy, though it has shown no disposition to attack them. This is an instinct, too, which, in a very remarkable manner, improves by being exercised, or perhaps we may say cultivated; for nothing is more common than to find an animal belonging to a species naturally mild and even timid, becoming bold in its attack both upon other animals and upon human beings, in proportion as these attacks are more frequently and more successfully repeated. This, of which the natural course is very easily seen, is what we are accustomed to call a vicious disposition in an animal. There is, however, no vice in a moral point of view in this, any more than there is moral virtue in its opposite; for it is merely the instinct of the animal excited and kept alive by exercise; and it does not differ in principle from the analogous instinct by which all animals find their proper pasture and their proper food, or by which wild ones return to their lairs or forms, or tame ones to their stalls and other habitations.

The usual mode of using the claw as a weapon, is striking out with the foot, in the same manner as other kicking animals use their hoofs; and from the great length of the leg, and the powerful muscles of the hinder part of the animal, the blow which it gives is rapid and very powerful; so that when the Australians course kangaroos with dogs, they require to train those dogs in the same manner as they are trained for coursing the emu, which also strikes out against its pursuer with great force and effect. The dog is trained to run, not on the direct line of the game, but a little to one side; and he continues until he can go in upon the fore part of the animal, in which part it is comparatively weak and defenceless. If, however, the enemy, or that which the instinct points out as being an enemy, appear suddenly in front, or in a situation where there is no means of escape by flight, the kangaroo does not tamely abandon itself to its fate. It adopts a new system of tactics, and this system is even more dangerous than the other, unless against an animal of considerable strength and weight. The kangaroo stands something like a tripod, upon the entire length of the very long soles of the hind feet and the point of the tail; which latter organ, from its stiffness and power of muscles, is scarcely less efficient than the other two. Thus posted on its tripod, and having some-

thing of the stability of a pyramid from the thickness of the hind parts and the slenderness of the fore, the kangaroo is really more stable and difficult to be thrown down than an ordinary animal of greater size and weight, when that animal rears on its hind legs. The bear, and such other plantigrade animals as have the habit of rearing their anterior part while they rest with the tarsi of both hind feet upon the ground, partake in great part of this stability; but as none of them have equal strength or efficiency in the tail, none of them are so stable as the kangaroo. It has often been remarked, however, how very firmly a bear can stand, and how large a weight it can carry clasped in its fore paws, when it is in an erect position; and it will readily be understood that the kangaroo will derive the full benefit of its superior conformation in this respect.

And it is worthy of remark, that though the kangaroo has none of the carnivorous propensity of the bear, its action at close quarters is not very dissimilar. Its fore feet are very short and feeble as compared with the hind ones; but they are so free in their articulations, that the fore arm can perform almost a complete rotation. They are furnished with five toes of unequal length, and each one provided with a strong and sharp claw, so that the animal can use them very effectively both in striking short blows at close quarters, and in hugging. In performing this last operation, the toe of the hind foot is sometimes brought into use, and used in ripping open the abdomen of the animal hugged; and as the great length of the hind foot, and the mobility of the tail, can give a firm base, though one hind foot is off the ground, this lacerating operation can be performed very certainly and very rapidly, and both the half savage dogs of the natives, and the better trained ones of the European settlers, are apt to be killed by kangaroos in this way.

These animals have still another mode of defensive warfare. When pursued, they betake themselves to the water, where they stand upon their tripod with only the body as far as the fore legs raised above the surface. In this situation they can very readily turn round as if on a pivot, and this facility of turning, together with their large and prominent eyes, enables them to command the horizon on every side, so as to front any danger that may present itself. If the enemy takes to the water and attempts to go in, the ready paws of the kangaroo seize it by the head; and, from the advantage of the structure and position, the animal is able to keep a large dog under water till he is drowned.

In the ordinary locomotion of the kangaroo, when undisturbed by danger, it leaps about rather than walks, generally using the tail to assist in the leaping. This leaping in its tranquil and unalarmed state is performed upon the entire soles of the hind feet; and the fore feet are not brought to the ground, except when the animal feeds upon grass, which it cannot do constantly, as there is little or no grass at any time in some of its haunts, and all of them are subject to have the grass burned up at some seasons of the year. On these occasions the fore feet are not brought to the ground at all, but employed like hands in bringing toward the mouth the branches of those shrubs and bushes upon which the animal feeds, when subsistence upon the ground fails it. Where, however, a more expeditious rate of locomotion is necessary, either for the safety or the pleasure of the animal, it can proceed by immense leaps, in the

taking of which it delivers its body from the points of the great claws of the middle hind toes; and as these are very strong, stiff, and sharp pointed, it gets so powerful a hold on any surface, however hard, that it can leap to a great distance, and recover itself and leap again with so much agility, that its march bears some resemblance to a rapid succession of short flights.

Altogether it is a most singular animal, both in the style of its action and in the instruments by means of which that action is performed. The region which alone it inhabits is, perhaps, in its physical character the most singular on the face of the earth, for the uncertainty of its climate and the singularity of its vegetation. For long periods of time, the atmosphere is without a cloud, and does not let fall a single drop of rain, so that the streams become dry, the larger rivers are in many places evaporated to a few pools in which the fish are huddled together, and a great breadth of the surface is plantless and covered with a saline efflorescence. From the extreme of this state of things, and without any other warning than that dismal murkiness which is the harbinger of great atmospheric changes in such places, the winds are let loose in tornadoes, and the rain descends as though the clouds had been pitchers shivered to pieces by the burning of the lightning, the bellowing of the thunder, and the fitful fury of the gusty storm. The winds themselves in such countries assume much of the majesty of thunder, for they sound upon the mountains as if the heavens were sown with hammers, and wrench and twist the trees, till even those species of eucalyptus, which are as hard as iron and as heavy as stone, are torn to shreds by internal shakes and fissures in their stems.

Amid this direful conflict of the elements, the earth upon every summit and every slope gives way; and mingling with the "torrent flood," it descends into the levels, or more generally floats onward in the swollen river to where that river meets the sea. At such times, the majesty of the main is in motion, as well as that of the atmosphere; and the yeasting surge flings back toward the shore those spoils of the land which would stain the beryl tint of its own waters. But the red-rolling flood of the swollen river presses onward on the other side, and the contending waters work the earthy deposit into a bulwark near the shore, behind which a certain quantity of the land flood is imprisoned; and this speedily converts the accumulated mud into a nursery for mangroves and other trees and plants which grow in the water; and thus at every violent storm there is formed near each outlet of the water a portion of new land totally unfit for the subsistence of ordinary land animals. In places a little more inland, the older surface of the earth is covered by a new stratum of stones, earth, and vegetable and animal remains, miscellaneous blended together, and often to the depth of several feet. Along with the remains of dead vegetables, there is a very considerable admixture of the seeds of living vegetation; and as those seeds are brought from grounds of different elevation and physical character from that on which the seeds are deposited, the same effect is produced as cultivation brings about when the seeds and germs of plants are conveyed to a more genial climate, and more abundantly watered soil, a vegetation entirely new springs up, and attains a most luxuriant growth in the course of a very short time.

While those violent changes and contests between the sea and the land flood are going on in the vicinity of the shores, there are other circumstances of a different character, but equally calculated for producing changes in the condition of the country, taking place in the interior. Though there are hills of considerable height in the island of New Holland, no mountains have hitherto been discovered, bearing any such proportion to the breadth of the country, as are to be met with in most other parts of the world. So far as it has been explored, the principal elevations are at no great distance from the shores; and thus, though it is probable that the quantity of rain in the interior of the country is not very great, yet a portion must reach the depressions in the interior. In as far as that interior has been explored, the rain which thus falls is accumulated in marshes or swamps, which are extensive pools of water immediately after the rain has fallen, but which gradually become dried up after the drought again returns. In warm countries, alternating waters of this kind do not produce even seasonal vegetation, for the drought burns up the marsh plants; and when this takes place, the volatile part of the vegetable matter evaporates, the salts are in great part left behind, and the soil is changed into dry sand or indurated clay, neither of which is well adapted for the growth of sea plants or land plants. In consequence of this, the soil gets worse and worse after every flood, and in a short time becomes wholly unproductive of any species of vegetation adapted for the food of an animal of even moderate size. Consequently the larger species of kangaroos are at all times confined to particular spots of the country—namely, the flats of considerable elevation, which are liable to be burned up at some seasons of the year, but never to be flooded. It becomes necessary that animals which have to find food on the vegetation of such places, should have a power of changing from place to place with considerable rapidity; and as, even when they are in the best condition, few of those places have that continual herbage which characterises our meadows, and adds so much to their beauty, they are totally unfit for animals which graze the breadth of the surface while they are in slow progressive motion. But the kangaroo, which, from its structure, can bound rapidly from tuft to tuft, and live upon vegetation of considerable height, as well as upon that which is immediately upon the surface, is exactly the animal adapted for such regions; whereas any of the ruminants would be incapable of subsisting upon them for any length of time. No doubt there are, to the south-westward of Sidney, pastures of considerable extent which have been found not ill adapted for cattle; but those pastures are situated on a part of the country which, in its geological structure, and its physical character, generally differs very considerably from what may be considered as the average character of the country.

The leaping motion of the kangaroos suits well with the nature of this kind of country, and though we are not so well acquainted with all the relations as to be able to judge with so much precision as to the advantages which they derive from the marsupial gestation, there can be no doubt that that also serves to fit them for the locality wherein they are situated, otherwise they would not have it, upon the principle in nature to which there is not one known exception—

that there is not an organisation or modification of an organisation, for which there is not an adequate use. There can be no question that the carrying of the young in the abdominal pouch, or marsupium, enables the female to move about and carry her young ones with much more ease than if any of her limbs were concerned in the performance of that office. The fact of the internal uterus and the marsupium admitting of a more rapid succession of generations than can take place in animals which perfect the young in the internal uterus, and afterwards suckle them on the teats, is also calculated to assist in keeping up the breed of the animals in situations where, without such a provision, they would be often exposed to the peril of extinction. Common placental mammalia, with single uteri, rarely have a case of superfetation in the uterus, and an impregnation during the time that the young are most exclusively nourished by the lactiferous secretion of the mammae, is scarcely less rare. Placental mammalia are therefore adapted only to countries in which they have irregular successions of seasons, unless in those animals that are not absolutely dependent on the production of green or recent vegetable matter for their food. The placental animals that occasionally furnish instances of superfetation, and also become gravid pretty frequently while they suckle, are almost, if not altogether, rodent animals, which eat bark and other dry vegetable matters, as well as the green produce of the earth. Perhaps the best and most circumstantial account which we have of the economy of the female kangaroos, is that which was read to the committee of science of the Zoological Society of London, by Mr. Owen, on the 26th of November, 1833; we shall therefore quote it for the information of such of our readers as have not access to the Reports of that most excellent and efficient committee. "Perhaps," says Mr. Owen, "there is no question in animal physiology that has given rise to more numerous and contradictory theories, and in which fewer facts have been well ascertained, than that which relates to the generation of the *marsupial animals*."

"In the present communication I propose to limit myself to the narration of some circumstances that have occurred in elucidation of this subject during a series of observations which I have made at the gardens in Regent's Park during the past summer.

"All the kangaroos at the farm were for this purpose transferred from the farm to the gardens at the latter end of June. The whole stock consisted of two males and six females, all full grown. The animals of different sexes were kept apart until they had in some measure become accustomed to the gaze of visitors, and reconciled to their new abode.

"It was to be expected that some accidents would occur in exposing so timid an animal, and one whose locomotion is of so violent a kind, to this change; and shortly after their arrival one of the females died in consequence of leaping against the wire fence. It is, however, probable, from the appearances observed on the post mortem examination of subsequent cases, that this, like the other individuals, were rendered highly excitable by great determination of blood to the brain. When the remainder had become more habituated to their new circumstances, the experiments were commenced, and the first step taken was to examine the pouches of all the females.

"The first female had previously been kept at the gardens, and had a young one, which measured about one foot two inches from the nose to the root of the tail: this, of course, had quitted the nipple and the pouch. The right superior nipple was the one in use; it was nearly two inches long and one-third of an inch in diameter, the gland forming a swelling on the base. The three nipples were everted, and about half an inch in length.

"A second female, from the farm, had a young one attached to the lower nipple on the right side. It measured about seven inches from the nose to the vent, was naked, with the skin of a bright pink colour, being still, in the language of M. de Blainville, a mammary fœtus. The nipple in use was one inch and a half long from the gland to the mouth of the fœtus; the rest were everted, and about the size of those in the first-mentioned female.

"The third female had a mammary fœtus about four inches long from the nose to the vent, adhering to the left lower nipple, covered like the preceding, with a naked vascular integument, which probably assists in oxygenating the blood. The eyes in this as well as in the preceding were closed. The other nipples were everted, but were not all of the same length, the right lower nipple being shorter than the right upper one. I could not ascertain when the female had been impregnated.

"The fourth and fifth females had no young in the pouch; all the nipples were everted.

"From this examination two facts were ascertained; first, that the kangaroo, at least in a state of captivity, has no particular period or season for breeding; and second, that the upper as well as the lower nipples are both used during the period of mammary gestation, and for the young animals subsequent supplies of nourishment.

"With respect to the second female, the following facts relative to her gestation were obtained from Joseph Fuller, head keeper at the farm. She received the male on the 14th of September, 1832. On the 14th of October, the same year, Fuller observed her looking sickly, and when the male approached her she scratched and repulsed him. This was about three p. m., when he was unfortunately called away on some business. In the evening, at eight o'clock, suspecting that parturition had taken place, he examined her pouch, and found a young one attached to a teat: on being touched the young one dropped off to the bottom of the pouch. Next day he again examined her, and found the young one adhering to the nipple. It fell off a second time on being handled, and both Joseph and Devereaux Fuller had the little one in their hands out of the pouch, and both assert that it was not more than one inch in length. It was again put in the pouch, and the mother was meddled with no more till the 3rd of November following. On that day Mr. Yarrell and myself visited the farm, and on hearing this account, we examined the female, and found the young one now three inches long, adhering strongly to the nipple. On further questioning Fuller on the subject, he said, that when first he saw the young one it was covered with blood-clot or coagulum; but on the following day it was quite clean and dry, and moved in body vigorously. The mother still suckles one of the previous year.

"From Mr. Morgan's experiments, it would appear, that when the mammary fœtus has arrived at nearly

the size of a fully grown Norway rat, it will bear a separation from the nipple for two hours, and regain its hold. According to Fuller's statement, it will bear a separation from the nipple and again become joined to it, at what is now proved to have been a very short time after uterine gestation; and Mr. Collie's observations, in the eighteenth number of the 'Zoological Journal,' are in confirmation of the same opinion. It is uncertain in what manner it regained the nipple, although in a subsequent experiment, where a similar fœtus was detached, the mother made many, but, as it appears, unsuccessful attempts to replace it.

"In order to ascertain precisely the period of gestation, as an essential guide to future experiments, the first female was selected, she being still suckling the young one of the previous year, and being known to be impregnated. She was placed with the male only at such times as they could be watched.

"The union was observed on the 27th of August at one p. m. She was separated from the male the same day, and was kept in a distinct shed and paddock until parturition took place. In order to enure her to the examinations of the pouch when they should become indispensable, they were repeated every morning and evening by James Hunt, the intelligent keeper, whose services were allotted to me by the council during these investigations. At many of these examinations I was present, and the following are among my notes made on those occasions.

"September 6th, tenth day of gestation. Pouch tolerably free from secretion; the right upper nipple about two inches long, and one-third of an inch in diameter; the young one, which has left the pouch, still sucking occasionally; the other nipples as when first examined.

"September 11th, fifteenth day. No alteration in the pouch or nipples; the young one still sucking occasionally.

"September 30th, thirty-fourth day. The young one that was sucking is dead. The nipple in use by it is begun to shrivel, and the brown secretion to form.

"October 4th, thirty-eighth day. Hunt observed the female in the afternoon putting her nose into the pouch and licking the entry. He examined her at six in the evening, but a slight increase of the secretion was the only perceptible change, and there was no appearance in the nipples indicative of approaching parturition.

"October 5th, thirty-ninth day. Hunt examined the female at seven a. m., and found the young one attached to the nipple. No blood or albuminous discharge could be detected on the litter, nor any trace of it on the fur between the vagina and orifice of the pouch. As the birth took place in the night, the mother had probably had time to clear away all traces of it.

"I repaired to the gardens the same day, and examined the pouch. The young one was attached to the left superior nipple; it resembled an earth-worm in the colour and semitransparent colour of its integument, and adhered firmly to the point of the nipple. It breathed strongly but slowly, and moved its fore legs when disturbed. Its body was bent upon the abdomen, its short tail tucked in between the hind legs, which were about one-third shorter than the fore legs; but the three divisions of the toes were distinct. The whole length, from the nose to the end

of the tail, would not exceed one inch two lines. A linear longitudinal mark of the umbilicus was apparent.

"It has been ascertained by Barton that the young of the opossum, immediately after birth, are in a much more imperfect condition than that above described in the kangaroo, being merely gelatinous corpuscles, comparable to a *Medusa*; but the observations of Dr. Rengger on an opossum (*Didelphis azarae*, Temminck), nearly allied to the Virginian species (*D. Virginiana*, Cuvier), accord, as to the condition of the new-born fœtus, with what we have now been able to ascertain with accuracy is the condition of the new-born kangaroo.

"Oct. 9.—I again examined the pouch; the young one was evidently grown, and respired vigorously. I determined to detach it from the nipple for the following reasons: 1st, to decide the nature of the connexion between the fœtus and nipple; 2nd, to ascertain, if possible, the nature of the mammary secretion at that period; 3rd, to try whether so small a fœtus would manifest any thing like voluntary action to regain the nipple; and lastly, to observe the actions of the parent herself to effect the same purpose, as we might presume they would be instinctively analogous to those by means of which the fœtus was originally applied to the nipple, supposing that to take place through the agency of the mother.

"An organic connexion by vessels between the mammary fœtus and the nipple being a necessary consequence of the truth of Dr. Barton's assertion, as to the condition of the product of generation at uterine birth, this has been much insisted upon; a discharge of blood has been described as a concomitant of marsupial birth; and even the anastomoses of the maternal vessels, with those of the fœtus, have been speculated upon (see *Mém. de Museum*, tom. ix., p. 393).

"The dissection of the mammary fœtus of the kangaroo by Mr. Hunter, showing the relation of the nipple to its tongue and mouth, the passage of the larynx into the posterior nares, the absence of the uracus and umbilical vessels, &c., tended indeed to disprove the theory of the vascular connexion; and the observations of Mr. Morgan and Mr. Collie, with the testimony of Joseph Fuller, were completely subversive of it. Nevertheless it was desirable to have ocular demonstration of the real state of the facts at this early period of the young animal's existence.

"It was removed from the nipple without the slightest trace of laceration of continuous vessels, or of any kind of connecting substance; but it adhered more firmly than I had been led to expect from Fuller. After it was detached, a minute drop of serous milk appeared on pressure at the point of the nipple; this was the smallest part of the nipple, and was not swollen or clavate; about half a line had entered the mouth of the fœtus.

"The young one moved its extremities vigorously after being detached, but made no effort to apply its legs to the fur or skin of the mother so as to creep along; it seemed perfectly helpless. It was deposited at the bottom of the pouch, and the mother was liberated and carefully watched. She immediately showed symptoms of uneasiness, stooping down to lick the orifice of the vagina, which she could easily reach, and scratching the exterior of the pouch with her fore paws. At length she grasped the sides of the opening of the marsupium with her fore paws,

and drawing them apart, just as one would open a bag, she thrust her head into the cavity as far as her eyes, and could be seen moving it about in different directions. During this act she rested on her tripod, formed by the tarsi and tail. She occasionally lay down, but in that posture never meddled with the pouch; when stimulated to do so, she immediately rose, and repeated the process of drawing open her pouch and inserting therein her muzzle, which she sometimes kept in for half a minute at a time. I never observed her put her fore legs, or either of them, into the pouch; these were invariably employed to widen the orifice, or in scratching the exterior. When she withdrew her head, she generally concluded by licking the orifice of the pouch and swallowing the secretion.

"After repeating the above act of insertion at least a dozen times, she lay down, and seemed at ease. When she had rested quietly about a quarter of an hour, we examined her again, and found the young one at the bottom of the pouch, but within two inches of the nipple. It was moving its extremities, and respiring as vigorously as before. I attempted to replace it on the nipple, but without success; it was therefore left in the pouch, and the mother was released.

"My engagements prevented me from visiting the gardens the day but one after this examination, when at ten A.M. I examined the marsupium, but the fœtus was gone. We searched very carefully every portion of the litter, &c., in the hope of finding it, but without success. I concluded, therefore, that the fœtus had died, and that the mother had probably eaten it.

"From what I observed of the mother after the separation of the fœtus, I should conclude that parturition takes place in the erect and not in the recumbent posture; and on perceiving the ease with which she can reach with her mouth the orifices of the vagina and pouch, a means adequate to the removal of the young from the one to the other became obvious. I should suppose the fore paws not to be used for the transmission of the fœtus, but to keep open the pouch ready for its reception, while the mouth would be the means by which it would be deposited therein, and perhaps held over a nipple till the mother felt the sensitive extremity grasped by the young one.

"This mode of removal is consistent with analogy. Cats, dogs, and mice transport their young by the mouth.

"I ought perhaps to have forborne this hypothesis when an opportunity of actually observing the process may so soon be afforded; but it was suggested by observing the actions of the mother after an artificial separation of the fœtus from the nipple, and accords with the phenomena better, I think, than any that have been previously proposed. There is no internal passage; there is no power of bringing the mouth of the vagina in contact with that of the pouch, either in the living or dead kangaroo, without lesion of the parts; the fore paws could not so effectually protect the embryo from the external hair on the lips, nor so safely ensure its passage; and the young one itself did not by any of its actions give the idea of its having the power of creeping up the fur along the pouch to the nipple.

"Where, however, the structure of the pouch, as in *Perameles*, and some South American opossums, is different, the mother's aid may be less necessary; but

the period of gestation being now ascertained, every endeavour will be made to clear up this part of the problem *ex vivo*."

Various species of kangaroo have been mentioned by different naturalists, but the distinctions between them are chiefly those of size and colour; and as there are several of them which have been described from an occasional sight of a single specimen, it is not easy to determine whether some of them may not be accidental varieties, and others variations of appearance arising from age, sex, or pasture. Under these uncertainties, we shall make our notices of the species very brief.

GREAT KANGUROO (*K. labiatus*). This is the most interesting species, the typical one, and the one on which the general descriptions are founded. Its proper native country is New Holland, where it is the largest native animal, and by no means rare in those parts of the country where there is a supply of food for it. Besides being the largest native animal, it is the favourite game both of the natives and of the European settlers; and the superior means of destruction possessed by the latter have thinned its numbers in all parts of the country which are even moderately peopled. In more remote places, the straggling settlers, whose cultivated patches are insignificant spots in the wilds around them, derive a good deal of their subsistence from the flesh of the kangaroo. We believe that the flesh of this, and indeed of all marsupial animals, is much inferior to that of placental mammalia living upon similar food; but the supply of human subsistence in the Australian wilds is so scanty and of such inferior quality, that the flesh of the kangaroo is considered as a dainty. The greater part of the flesh is accumulated on the hind quarters, so that when the hunter has a long distance to return home, he sometimes leaves the fore part of the animal to the carrion birds, and takes with him only the hind quarters and the skin, which is made into leather and used for various other domestic purposes. The favourite mode of dressing the flesh is by making it into a sort of stew, which is provincially termed a "steamer;" and those who have partaken of it, seasoned by the sauce of a thirty miles' scramble in the woods and wilds, describe it as being by no means unpalatable.

This species varies a little in the colour, but in general it is of a reddish ash grey on the upper part, white on the under, with a grey streak across the chin; and the legs and upper side of the tail blackish. It is an animal of considerable size, sometimes attaining a height of six feet, which, however, is to be understood of it not as standing on all fours, but as erect, or resting on the soles of the feet and the extremity of the tail. It was discovered by Captain Cook in 1789, and it has been introduced, and is bred readily, in Britain and in other parts of Europe; and it has also been introduced into the grounds of several of the more wealthy settlers in the neighbourhood of Sydney. Its singular appearance and habits attract some attention, and it no doubt forms a variety in a park; but it is neither a pleasant nor a profitable animal. It appears to be almost, if not altogether, destitute of that sensibility to kindly treatment and gratitude to those who treat it well, of which not even the most ferocious, or separated from man in their habits, of the placental mammalia are not altogether destitute. There are instances mentioned of the lion yielding his ferocious disposition, and not

only playing with those who fed and attended him, but even making pets of small animals; we have also some recorded instances of the delight expressed by the Hyæna on recognising one who had formerly been kind to it, even after a separation of many months; nor are there wanting instances in which the seal has voluntarily left its native element to visit the abode, sleep on the couch, and watch, with all the vigilance of a dog, those who have treated it with kindness. No such affection, and indeed nothing that can be called affection at all, has ever been displayed by the kangaroos. It is perfectly indifferent to every species of treatment, and will attack just as readily those by whom it is fed and attended as those who treat it harshly. This appears to be a general character of marsupial animals. They evidently belong to a lower order of animalisation, if the term may be allowed, than those animals which mature their young by internal gestation. None of them have much courage, or apparently many resources; and those which approach the nearest to the carnivorous animals in their dispositions are scavengers rather than hunters. Some of them tear sheep in a most unscientific manner, so to speak; for instead of first killing and then eating the animal, as is done by the members of the dog or cat family, they set about tearing and eating it alive, at any one part they happen first to get hold of; and we believe it is not unusual for some of the genus *Dasyurus* to gnaw off the tails of sheep and young cattle, on their nightly prowlings, without daring to assail any other part of the body. One might perhaps expect this conduct from the marsupial animals, for there is unquestionably a physiognomy of animals as well as of human beings. It is difficult to reduce this physiognomy to system, and to point out the specific disposition which the eye and the air of an animal indicate; but still there is not the least doubt that if there is spirit in the animal there is always speculation in its eye, and if there is energy in the action of the animal, that energy will tell in its attitude, even when it is in a state of repose. In so far as one can judge analogically of this indication of the disposition of animals from their expression, it may be said that the susceptibility of the animal is always in proportion to the extent of change which the expression of its eyes can undergo; and in the case of the kangaroo, and indeed of all marsupial animals, so far as is known, there is little, if any, change of this kind. One might address the whole race of them in the same terms as Macbeth addresses the ghost of Banquo:—

Thou hast no speculation in those eyes
Which thou dost glare with.

For under the most kindly and the most cruel treatment, they have the same blank and vacant expression; and though kangaroos are very prone to do mischief, they do it without any previous sign of excitement, much in the same manner as if they were passive engines. Some of the marsupial animals, it is true, never offer any violence to human beings; and the wombat and the koala may be beaten without showing the least disposition to retaliate, and hardly any even to escape. They are thus usually denominated gentle creatures; but their gentleness is something analogous to the gentleness of a stone, which breaks no one's toes unless it be run against, and the injury be the act of the sufferer. It is in fact the passiveness of stupidity, and a very strong evidence

that the animal is susceptible of scarcely any cultivation.

This is exactly the case with the kangaroo ; so that after the first wonder at its strange shape and unique style of motion is over, there is no more interest about it ; for there is no disposition in it which can be drawn out as the basis of that sort of attachment, which can be formed with almost any placental animal, by a careful study of its disposition, and due attention to its comfort. The kangaroo is, therefore, in its very nature, an animal of savage climes ; and it is not a little singular that, in a large portion of the earth's surface, which is as peculiar in most of its productions as it is large, the principal four-footed animal and the aboriginal human being should be at the very bottom of their respective races. Such, however, is the fact ; and it appears to be just as hopeless to attempt civilising the native New Hollander, as to attempt taming the kangaroo. Some of those natives have been educated, some of them have been treated with kindness, some have been employed in various offices ; but in almost every case the result has been only an increase of cunning, and a deepening of vice ; so that the parties were in the end no more to be trusted than their naked brethren, who lie in wait in the bush for the purpose of spearing every living creature, human or not human, which happens to pass by. This is a very curious point in physiology ; but it is one, upon the discussion of which, we, for obvious reasons, cannot in the meantime enter. But still we may remark, that no people have ever been civilised by intercourse with other people, except such as had previously shown some disposition to civilise themselves. So, also, among the lower animals, there is no hope of taming, into anything like attachment, any animal which does not show some resource and stratagem in a state of nature ; but if the human being, or the other animal, evinces the requisite capacity, there is always a way of turning that capacity to the very best advantage, how much soever it may be misused, or turned to vice, before the treatment is applied to it. If, however, there is no capacity, mere brute placidity is no recommendation ; and it is from its total want of this capacity, together with its indiscriminate disposition to do mischief without any apparent cause, that we have described the kangaroo as an unpleasant animal to be kept in parks or pleasure grounds. Indeed, we have direct evidence of this fact ; for some which were in the royal parks in this country were so very vicious, without any obvious cause, that it became necessary to remove them ; and we believe that some of those in the menagerie of the museum at Paris were very prone to attack and lacerate the keepers ; and the wounds which are inflicted by their claws, are far more formidable than single cuts given by almost any other animal.

In addition to this, we mentioned the inutility of the kangaroo as a domestic animal. From its structure, it cannot be employed in any species of work ; and the useful products which it furnishes are few in number. Its skin is of some value, though perhaps not equal to that of most ruminant animals, and certainly not at all to be compared with the skin of the horse. From its peculiarity of structure, and the mode in which it rears its young, it can be of no use whatever as a milk animal ; and its hair is neither fit for spinning nor for felting into a fabric of any consistency ; so that the only part of it which has value, is its body in substance. The principal part of that is

the flesh of the hind quarters, as already stated ; and this flesh is wholly unmixed with fat. There is, indeed, a sort of soft fat which accumulates in the rump and the upper part of the tail, to which Australian epicures give some praise ; but it is almost, if not entirely, destitute of stearine, and thus unfit for those purposes in the arts, to which the surplus fat of our domestic animals is applied. The portion of the carcass, too, which is fit for food, is so small that, in a country where land and its produce are of much value, the kangaroo could not be bred so as to anything like repay the expense of its keep. These circumstances put the use of it, in an economical point of view, entirely out of the question ; and from what we have already stated, it is not more desirable considered as an ornament ; and, therefore, the only purpose which it can answer with us, or in any other European country, is that of being kept in zoological collections of living animals, as an object of science or simply of curiosity ; and certainly, in both of these respects, it is highly interesting, and deserving of its place.

It is a singular fact, and one which, while noticing this animal, we can hardly pass over, that, in every country where the inhabitants have been found in a low state of savageism, there is hardly any animal available for domestic purposes. When America was discovered, there was not, with the exception of the lama and alpaca, in the central mountains, any animal calculated to be of service to man ; and in Mexico, and more especially in Peru, where those animals were kept in a state of domestication, and partially at least used as beasts of burden, there was an incipient civilization, rude indeed, but still forming a wonderful contrast with the condition of the people in other, and naturally far richer, parts of the American continent. In all the points of their character, the native inhabitants of many of those districts in which, when first visited by Europeans, there were no domestic animals, were not only superior to the Peruvians, and especially to the Mexicans, by whom civilisation had been begun, but many of them, those of the north especially, and also some of those of Paraguay and Bolivia, are superior to the average of European peasantry, both in energy and in mental resources. Yet they had not become civilised even when people of less natural endowments had made some advances ; and we can account for this apparent anomaly only in the fact of those superior people having no animals which they could tame and turn to account in their domestic economy.

This is a very important fact, as showing the dependence which the development of the human powers has upon the situation in which human beings happen to be placed, and from this we may, without impropriety, infer, that the people of the east owe their advances in civilisation more to the possession of the ox, the sheep, the horse, the ass, and the camel, than to any mental superiority on their part. The coincidence of elevated character with the possession of those animals, and of the absence of that character with the want of them, are too general, we may say too universal, for admitting us to suppose that they are owing to accidental circumstances ; and this consideration should teach us not only not to be wantonly cruel to those animals, but to look upon them with kindness, and pay every attention to their comforts, as they are unquestionably our benefactors. This is a subject upon which little has been said, though

much might be said, and even requires to be said; but we must leave it in order briefly to notice the other species or varieties of kangaroos which are mentioned by writers on zoology.

Great Kangaroo.

The great kangaroo, to which the above observations apply, appears to have been multiplied into two species; one more inland and northerly, to which the description of colour which we have given applies, and one more southerly and near the shores, which has been called the sooty kangaroo, but which differs from the former only in being rather larger in the size and deeper in the colour. It is described as being sooty brown on the upper part and reddish grey on the under, with red on the flanks; and the feet, the point of the muzzle, and the legs, blackish brown. It is probable, however, that these distinctions are nothing more than those between a mature animal in a favourable pasture, and a young animal in a pasture less favourable.

GRAY KANGAROO (*K. griseus*). This species, if distinct species it be, is considerably smaller than those which have been mentioned, for it has not been observed of greater height than three feet and a half. Its general colour is reddish grey, with white points to the hairs, the colour becoming paler towards the under part, and passing into white on the middle of the belly, while it gradually deepens toward the mesial line of the back. The legs are brownish grey, and the terminal part of the tail is reddish brown. The ears are not so pointed as in either of the two species, or varieties, which have been mentioned. Like them it is a native of New Holland, and nothing is known of its manners as distinguished from those of the others.

RED-NECKED KANGAROO (*K. ruficollis*). This is still smaller than the former species. It is grey, with more or less of a reddish tinge on the upper parts and the flanks; but the lower part of the neck is deep red. The insides of the limbs are white, and so is the middle of the under part of the body, but the white on the latter is of limited extent, of not more than a mere line. One of its most remarkable characters, in as far as mere colour can be considered a character, is the colouring of the tail, which is russet grey on the under part and whitish on the upper. The ears are of the same colour as in the great kangaroo, but of the same shape as in the grey one, so that it is possible that this may be merely a hybrid between the two. Hybridation, in kangaroos par-

ticularly, and in marsupial animals generally, is a subject to which little or no attention has hitherto been paid, and yet it is one of very great interest, in coming to a proper knowledge of the physiology of those singular animals. The male kangaroos have not that bifurcation of the organs which is possessed by many of the marsupial animals; but the females have the compound uterus, and are capable of impregnation while enceinte of a previous fetus, not only in the marsupium, but in the internal matrix. The fact has not been ascertained, but those circumstances would lead us to conclude that there is not a regular animal season of heat in the female kangaroo, but that the animal is as passive in the matter of reproduction, as it is indifferent to kindly treatment. If such is the case we might conclude that hybridation would be very common among such animals, and that they would break down into very many varieties; and until these points are settled, the distinction and description of species must remain very vague and unsatisfactory. It indeed appears that, in the natural history of marsupial animals, error has all along been committed, in consequence of our judging of them by the standards which had been previously formed from the examination of placental animals; and unless we get rid of this false analogy, and study the marsupial animals upon data furnished by themselves, we shall never be able rightly to understand their nature, or to form a proper judgment of their economy. For the reasons now stated, we shall omit several of the species which have been enumerated by writers on the subjects.

WOOLLY KANGAROO (*K. laniger*). This is mentioned by the French naturalists Quay and Gaimerd, and was found by them in Australia, but if it exists as a species it is very rare. It is described as being about the same size as the great kangaroo. The head, the neck, the back, the flanks, the outsides of the legs, and the upper side of the basal part of the tail, are bright red; and all the rest of the body is white, with the exception of the ears, which are grey, and the toes, which are russet brown. The hair on the body is described as being very long and woolly, resembling that of some of the American members of the camel family; but so little is known of the animal that it is impossible to speak with precision concerning it. It is described as being found in the western part of Van Diemen's Land, where the country is very mountainous, covered with woods, and subject to violent falls of rain; and it is by no means impossible that those circumstances of the country and climate might induce as great a change in the covering as appears between this and the kangaroos with short hair; for we find that similar changes are induced in the mountain cattle of our own country, more especially in those districts which are subject to heavy falls of rain. Indeed, the effect of difference of situation and climate upon them is one of the points upon which we need additional information before we can come to any positive decision as to what is or what is not a species of kangaroo.

BRUSH-TAILED KANGAROO (*K. penicillatus*). This is another species which is but little known, though there is no doubt that it exists. It is found beyond the Blue Mountains in the interior of Australia where it does not appear to be common, and we are not aware that it has been met with near any of the shores. The upper part is grey, of different shades,

and the under part reddish brown. The head dark grey, with a mesial line of deeper colour; the cheeks and throat marked by spots of a pale tint, the feet dark coloured, and the tail as long as the body, and furnished with a thick brush or tuft of hair at the extremity. The muzzle is much more slender than in those kangaroos which are more abundant, and the corners of the mouth are furnished with whiskers consisting of a few long and stiff hairs. The animal has, however, been so seldom seen, that the accounts of it are very imperfect, though we believe that the museum of the Linnæan Society contains at least one specimen.

BANDED KANGUROO (*K. fasciatus*). This species is of a grey colour, with a brown band across the back and loins. It was known as early as the time of Dampier, and it has been repeatedly observed since. It has many peculiarities both of form and of structure, which appear to entitle it to rank as a species. The muzzle is much shorter and the head rounder than in most of the others, and altogether it has a more elegant appearance. Though we have stated the general colour as being grey with brown on the back and loins, yet there is so much effect in the markings and contrasts of the colours, that it has sometimes been styled the elegant kangaroo. The hinder part of the body is very generally marked with transverse streaks of grey, red, and black, which contrast boldly with each other in some places, and are blended in others so as to give it a very rich appearance. The outsides of the legs and the muzzle are deep red, and the under parts and the tail grey, with the exception of the tips of the latter, which is black. This species has been met with only on the east coast of New Holland, near the sea shore, or on some of the small islands which are found on that coast; but, as is the case with all the rest, it is scarcely possible to study its habits in a state of nature; and the few specimens which have been obtained were shot, so that little or nothing is known of it except as a dead animal. It is described as being rather smaller than the common kangaroos, which are often met with living, and with whose manners we are, at least, a little acquainted; but still, as there appear to be climatal varieties in other parts of Australia, and as we are uncertain what changes may result from crosses between the varieties of different regions, which may frequently meet in a country so much burnt up during the long droughts, and where animals are necessarily so much put to their shifts, we can come to no positive conclusion concerning it.

There are several other species named by the French naturalists that visited Australia and the islands in the adjoining seas; but as, on some occasions at least, they appear to have gone more for the purpose of naming, than for that of discovering and discriminating, the accounts which they published, and which have been repeated again and again, cannot be depended on; neither can we be certain that the different specimens of animals which they brought, on very casual visits to a most extensive country, of which they saw only limited portions of the shores, are distinct species, or even varieties, or merely the same identical species in different stages of their growth and different states of their colouring. That the scientific men who went out on these occasions were talented and zealous in their vocations we have not the least reason to doubt; but

it so happened that while France was politically at war with this country, some of those expeditions went out for the express and avowed purpose of taking by storm every English name which had been given to a place, an animal, or a thing within the limits of the territory, and substituting a French name in its stead. Accordingly we find some of the most ludicrous geographical puzzles in the translations which have been made from the reports of those visitors, into compilations on natural history published in this country. Those translators and compilers are, generally speaking, marvellously unencumbered with knowledge, and especially with geographical knowledge; and as the English answering to those French names is not to be found in the dictionary, and as the names themselves are now forgotten even in France, we often find an animal set down as an inhabitant of some place which has no existence.

In as far as the British residents within the colony are concerned, the natural history of Australia was, till within these few years, vague and imperfect enough; for the chief persons that ranged into the fastnesses of the country were those expatriated outcasts of Britain, at whose hands a taste for anything but the gratification of their animal passions at the least possible expense of labour could not be expected.

Of late years, however, there has been much improvement; and those who are interested in the knowledge of nature—and who, being capable of thought, can fail in being so interested—are deeply indebted to the Zoological Society of London, which has given concentration and vigour to the science of living nature, has enlisted very many officers of the army and navy among its corresponding members; and they most commendably keep up that energy and enterprise which are at once the province and the glory of their callings, by extending our natural knowledge of the several regions in which they reside. In so far as Australia is concerned, there is still only a beginning in proportion to what we may ultimately expect; but still a beginning is the step, and that being taken, we may feel confident as to the progress. Through their agency, and the investigations of scientific men at home, the perplexing anomaly relating to the ornithorhynchus has been cleared up; and we may confidently hope that ere long the very peculiar zoology of our Australian colony, the most extensive in mere breadth, will be elucidated in a manner honourable to Britons and instructive to the whole human race.

KANGUROO RAT (*Putoroo*). A genus of marsupial mammalia, found in New Holland; and though differing in some essential particulars from the kangaroos, properly so called, yet agreeing with them in some respects. There is only one animal of this genus, so far as has been hitherto discovered; but it has had the advantage of many names, if that can be considered an advantage. Dr. Shaw, whose judgment was seldom so praiseworthy as his industry, and who, we believe, was among the first into whose hands it came, called it the little kangaroo (*Macropus minor*). Illiger, we believe, gave it the name of *Hypsiprymnus*, which means "elevated rump," from the great length of its hind legs; and the colonists of New Holland call it the kangaroo rat. The first part of the name being founded chiefly on its form, and the second on its size. It is, however, a distinct and peculiar animal, and perhaps a better name for it cannot be found than *Putoroo*, which it is called by the aborigines of

New Holland, the last syllable being strongly accented and much prolonged. It is from this that the systematic name which we have adopted is derived. The structure of the teeth in this animal is peculiar, and indicates a miscellaneous figure, the same as many of the rats are, though its chief subsistence is understood to be vegetable. It has six incisive teeth, two canines, two false grinders, and eight true ones in the upper jaw; the same number of grinders, true and false, and two incisive teeth, in the lower jaw, but no canine teeth. The upper jaw, therefore, partakes more of the character of a carnivorous, and the lower more of that of a rodent animal. The first incisive tooth in the upper jaw is much longer than the others, and also stronger, and has three rounded protuberances in the front side; the second tooth is small, and resembles the teeth of the carnivorous marsupial animals. The last tooth of the superior incisives is very small; and there is a vacancy between them and the teeth in the rear, by which means it approaches still more to the rodentia. The hind legs are much longer than the fore ones; the feet on them want the thumbs, or fifth toes; and the two inner toes are united nearly in the same manner as in the kangaroos. The tail is long and very stout; and the marsupium in the females is complete, but contains only two mammæ, at least in the specimens which have been examined with sufficient care; but it is possible that, as is the case with various marsupial animals, these appendages may wholly or nearly disappear when not required, and be developed only as they are wanted.

It is understood that, notwithstanding the trace of carnivorous character in the teeth of this animal, its food is wholly vegetable, and it lives indiscriminately upon green herbage and upon dry, the peculiar structure of its incisive teeth enabling it to gnaw the latter in the same manner as a rat. They live concealed among stones, or in the bush, or thick shrubby underwood, which is so common in that part of the world; and the sound or cry which they utter is very similar to that of the rat. From the length and strength of their hind legs, as compared with the fore ones, they are very dexterous and powerful leapers, although in regular motion upon all-fours they are far from being so swift or graceful as the common rats. They are very numerous, especially in the rocky and bushy parts of the south of New Holland; and it is not a little curious that not only the marsupium, but the form of the kangaroo, is preserved in this, which is almost the smallest native quadruped of New Holland. This fact, that the whole of the mammalia of that country which are vegetable feeders, should be leaping animals, and not walking ones, is by no means an unimportant key to the physical geography of the country. When the herbage, or surface of vegetation, is continuous and perennial, as it is in those extensive plains by the banks of the great rivers, the grazing animals are generally of large size and slow in their motions, not given to migration, and having no occasion for it. This was the case with a great extent of North America at the time when it was discovered by Europeans; and it is now the case with many of the plains of Central and Southern America, where cattle from the east have been introduced. Near the borders of the great desert again, which stretches obliquely from south west to north east, over great part of the breadth of Africa, the different regions are periodically burnt up in the drought; but become

fertile, and covered with a herbage which is nearly continuous, after the rain sets in, which it does differently in the different latitudes. This is the appropriate pasture for ruminants of lighter make and fleet limbs; and accordingly we find that it is the grand resort of the numerous and beautiful family of the antelopes. When the pasturage is still continuous, but lies upland, so that its quantity is not so great as in the places to which we have alluded, it becomes the proper pasturage of the sheep; and when we get to a still higher elevation, or more broken ground, where rocks and precipices alternate with patches of verdure, we come to the natural locality of the goat, which is the last ruminant animal on the cliff, in like manner as the antelope is the last one on the margin of the desert; but all these animals belong to one class, and form a regular succession from the ox to the goat on the mountain, or the antelope in the desert; and there is no resemblance among them to any of the marsupial animals which graze. The characteristic ones of these are found only in Australia, where they leap from patch to patch, and can partially use their fore paws in the eating of their food. In countries where there are browsing animals which consume the green leaf of the ground vegetation, there are ground animals of the rat family, which, in great part, live upon the fallen seeds; and just as we find the kangaroo taking the place of the ruminants in Australia, we find the kangaroo-rat partly occupying the place of the common rat, and other rodentia represented by species of marsupial animals which, like the kangaroo-rat, are not so decidedly herbivorous as the typical kangaroos, and yet not, strictly speaking, carnivorous animals, but miscellaneous in their feeding.

The kangaroo-rat is about the size of a small rabbit. The body rather exceeds a foot in length, and the tail is fully a foot. The fore legs are only between three and four inches long; but the hind ones measure as much as ten inches. It is a very gentle and timid animal, very easily tamed, but not particularly interesting in its manners. It is eaten by the aborigines, who are not very choice in their feeding; but its flesh is small in quantity, and inferior in quality.

KENNEDIA (Ventenat). A genus of climbing plants, natives of Australia, belonging to *Leguminosæ*. Generic character: calyx two-lipped, upper lip two-toothed, lower one three-cleft; standard reflexed; pod linear, compressed, contracted between each seed. This genus are favourite green-house plants, grow freely in a mixture of loam and peat, and are propagated by cuttings.

KERRIA (Decandolle). An ornamental deciduous shrub, said to be a native of Japan, belonging to *Rosaceæ*. It is of the easiest culture, and has lately emerged from the green-house into the open air. When first introduced it was called *Corchorus Japonicus*.

KIDNEY BEAN. Is the *Phaseolus vulgaris* of Linnæus, a well known culinary vegetable. There are two principal species in our gardens viz., annual dwarfs and runners, the pods of which are used when green and tender. Those of the dwarfs are also a favourite pickle. The runners, both scarlet and white flowered, are at once ornamental and most useful plants, being very productive, and continuing to yield pods till killed by frost: for, being tropical plants, they are extremely impatient of the least degree of frost. The runners are, properly speaking,

perennials, but as such they are of no use in this country, as they do best when raised every year from seeds. The *Haricots* of the south of Europe, and the *Garacallas* and *Callavances* of tropical countries, all belong to this genus.

KIGGELARIA (Linnæus). A genus of ornamental trees, natives of the Cape of Good Hope, belonging to the natural order *Flacourtiaceæ*. They are treated as green-house plants, and propagated by cuttings.

KITE (*Milvus*). A genus of diurnal birds of prey, not very numerous in species, but very generally distributed over the world, plentiful in those places of the country which are favourable to its habits, and resorting more frequently to the vicinity of human abodes than most birds of prey, and therefore better known. In some countries, kites are objects of persecution, from the depredations which they commit on the young of the poultry yard and the duck pond; while in other parts of the world they are protected on account of the great number of offensive small animals, of which they clear the neighbourhoods of houses.

Kites form a very distinct section of diurnal preyers both in their appearance and in their habits. Their tarsi are slender, but at the same time short; and, therefore, though they exceed the sparrow-hawks in size, they are not nearly so powerful with the foot, neither are they so courageous. The bill also is smaller and weaker in proportion to the size of the birds, than in any of the hawks or eagles; and altogether they indicate a feebleness of action, and smaller prey. At the same time, however, they are very ravenous, as well as very miscellaneous feeders; and when a hungry kite meets with an abundant meal, it feeds so eagerly that it may be knocked down with a stick, or even seized with the hand, in which respect it bears some resemblance to several of the vultures. But notwithstanding its comparative feebleness and its voracity, a kite is by no means an unhandsome or uninteresting bird. On the contrary, its motions in the air are so light and graceful, and its style in hovering about is so easy, and performed with apparently so little effort, that it is assumed as a sort of typical motion. Kite-flying is a cant term for the putting of light or doubtful things afloat in the world; and there is not a schoolboy who is not acquainted with the paper imitation of this light and graceful hoverer in the sky; and though, in the case of the paper kite, the string is the resistance which enables the expansion of the kite to rise and ride obliquely in the air, it is the weight of the living kite, balanced against the ample expansion of its wings and tail, which enables it to float, occasionally at least with little more apparent muscular effort than its paper namesake. We shall best describe its manners, however, in adverting briefly to the species.

THE COMMON KITE (*M. vulgaris*) is the only species which is found in the British islands, or indeed in Europe. But, as is the case with most birds of prey, the young are different from the mature birds in the markings of their colour; and, on this account, they have sometimes been brought from foreign countries, and described as species inhabiting there.

The kite is rather an extended bird. The female measuring more than five feet in the extent of the wings, and about half as much in the length of the body and tail, the latter of which is very much forked, and pointed in the branches of the fork, so that while

beating about, the bird can wheel and turn on the points of the forks as on centres. The exterior feathers of the tail are upwards of a foot in length. The wings are not so pointed as the tail, but they are pretty strong in proportion to their other dimensions. The third and fourth quills are the longest in the wing, the fourth being a little longer than the third. Of the others, the second is a little shorter than the fifth, and the first much shorter than the sixth. This arrangement of the feathers gives a balance to the middle part of the wing, by making it, though really a pointed wing, take a strong hold on the air, by means of which it performs the double offices of wheeling and floating much better than if it had been wholly adapted for either of them. The kite is a light bird in proportion to its extent, being usually in the female not much more than two pounds and a half, while the male is smaller and less heavy.

In the full grown bird, the head is dull white, streaked with dusky lines; and the feathers on the neck are pointed, and capable of being partially erected. The upper parts are brown in the centre of the feathers, and reddish orange on the margins; the under parts are reddish orange, with stripes of dusky brown on the thighs and belly. The female is not so brown as the male bird, and there is often a tinge of greyish ash in her general plumage. The young, before arriving at maturity, is much redder, the male bird especially, than the full grown; and it is in this state that it has been described as a different species; though there is often so much difference of tint in the male and female when full grown, as to have procured for the one the name of the red kite, and for the other that of the grey kite; but they are the same species notwithstanding this, and we have no certain evidence that there is any specific difference of kite in Europe; and the same species with which we are familiar in this country is found in many parts of Asia and Africa.

The kite is indeed a ranging bird, not only in its ordinary feeding, but, as is generally understood, in seasonal migration. In winter it is but rarely seen, and seldom if ever in the neighbourhood of farm-yards and houses; for as it has not sufficient courage for attacking full-grown fowls, it does not pay its visits until the spring broods are hatched. All birds of prey are comparatively little seen abroad over the fields during the winter. The resident ones are then chiefly in the fastnesses of the woods and wilds, which are much more productive in the winter season than the open grounds, both for the preyers and the animals on which those preyers feed. On this account it is often supposed that species quit the country during the time when they live in concealment in it; but notwithstanding this, it is probable that, in some parts of Europe at least, kites may migrate during the winter, and resort to Egypt, which is then the general retreat of very many birds. This opinion was maintained by the ancients, and the kite is enumerated among those birds which appeared in numbers in Greece during the spring; and Greece is known to be a great resting place for birds, both in their northward and southward migrations. It is not understood that the same constancy of attachment is found in the kites which characterises, in so remarkable a manner, those diurnal birds of prey which are known to be permanent residents, and which form an interesting feature in their character. Male kites, though not the most warlike of birds, yet sometimes exhibit con-

siderable symptoms of pugnacity during the early part of the pairing season. Their strifes have not the dashing style about them of those of the gallinaceous birds, nor even of the ruff, but still they do contrive to pull and scratch at each other; and as this is certainly not done in order that the victor may eat the vanquished, we can assign no natural cause for those battles except that they are affairs of honour connected with the females; and as it rarely happens that there is any battling of this kind between animals which are constant in their pairing, the most rational conjecture is, that the pairing of the kite continues for only one brood.

Considerable labour is bestowed in forming the nest, and no little of instinctiveness in the placing of it. It is usually in the fork of a thick tree, where it is concealed by the natural branches; and it is more elaborate than the nests of birds of prey generally. The external part is formed of twigs, thickly wattled together, and the interior is lined with wool, hair, or other soft and warm matter. The eggs are generally three in number, fully larger than those of the domestic hen; they have sometimes a few dark blotches near the thick end, but at other times they are all over of a dull white colour. The young remain a long time in the nest, and as they feed greedily, the old birds, more especially the female, have severe labour in finding food for them; and it is during this time that they invade the farm-yards with the greatest audacity, though even then they do not venture to attack a bird capable of showing any resistance.

The kite, though its motions in the air are free and graceful, is not in the habit of preying there, even for any sort of creature. It feeds on the ground, or sometimes even on the surface of the water, from which it can twitch up a floating animal substance with great dexterity. It is on the young of the most timid animals that the kite chiefly feeds, the young of all descriptions of game birds, and also the young of hares and rabbits, and on lambs in the very early state, more especially if they are sickly. Mice, insects, worms, and snails, it attacks and destroys in vast numbers; and no kind of carrion comes amiss to it. This last property recommends it to the protection of the inhabitants of those towns which are in warm countries, where putrefaction comes on rapidly. In Turkey, and also in some parts of Egypt, it enjoys a sort of domestic life in this way. The birds are numerous, hovering about, or resting on the houses, and they are instructed so that they answer to a whistle, which is the signal for them to descend and clear the ground. Kites are seldom seen in or over towns in any part of Britain at the present day, but the case was different formerly, when less attention was paid to cleanliness. Not longer ago than the time of Henry VIII. numerous kites supplied the trade of scavengers in London; which trade was found a nourishing one for them, and a necessary one for the people. Indeed, in all countries where cleanliness is neglected in towns there is a necessity for scavenger birds, and for kites among the rest, which ceases when there is a better system of management; and in those towns of the east and south which are still subject to infectious diseases, there is no doubt that those diseases are rendered less frequent than they would be by the labour of those birds; and the rapid motion, the quick eye, and the ravenous appetite of the kite, conspire to render it one of the most serviceable of the whole.

But it is in the free air where it has scope, and its necessities require the complete exercise of its powers, that the kite appears to the greatest advantage; and therefore we shall quote a short description of it from Mudie's "Feathered Tribes of the British Islands." "The kite," says Mr. Mudie, "has, from the extent of its wings and tail, very great command of the atmosphere and possession of itself in that element. It does not beat along in straight lines, but wheels in curves, which it is constantly opening and closing, and always in a smooth and graceful manner, without any jerks; and if it were possible to trace a day's path of a kite, it would be a very fine specimen of looped curves. The kite can hover a long time over the same spot, with very little exertion of the wings, and though there is a fresh breeze; and there are times (probably when it has lost sight of some prize on the ground, or discovered that the prize over which it was hovering was no prize at all) at which it will 'give itself to the wind,' and drift to leeward in very beautiful style, and apparently with complete self-possession. Crows often do the same, especially upon the elevated moors, where prey is but scanty, and they have been long contending with the wind. Kites will also sometimes turn down the wind to escape the more powerful falcons, which, though they do not attack the kite, often frighten it, and make it lose its prey; and as going down the wind is not a habit of the falcons, the kite gets away from them by the manœuvre. That manœuvre, though held in great contempt by the falcon, is by no means an ungraceful or uninteresting one: the bird rides lightly on the wind, but retains its self-command, so that it can take a new direction whenever it pleases. The axis of its body is placed at an angle to the wind, which is smaller in proportion as that is stronger; and the windward wing is elevated, so that the wind takes the under at an angle, and tends to raise the bird obliquely upward while its weight presses downward and counteracts. When looked at, the bird always has, in these cases, the appearance of descending as it drifts. But that is an optical deception, for all things that are higher than the eye appear to descend as they recede, even though they are rising; and the kite may often be observed to have gained height, while thus appearing to float downwards. If on those occasions an alarm is given, the bird hauls closer to the wind and makes off."

The kite, from its peculiar appearance, and even from its predatory habits, is a bird which has attracted very general attention, and in consequence received no inconsiderable number of provincial names. One of the most common of these, and also one of the most descriptive of the general air of the bird, is the "glead," differently pronounced in different parts of the country; but always having the same name, being formed from the active participle of the verb to glide or slide along smoothly. But in many districts a qualifying epithet is thrown in; and it is styled the "greedy glead," the adjective being as expressive of its general appetite as the substantive is of its air and manner when floating on the wing.

SWALLOW-TAILED KITE (*M. furcatus*). This is an American species, and has been sometimes described as a hawk, and sometimes as a kite. It is chiefly insectivorous; and its gliding habit and power of turning are certainly more rapid, though not so soft as those of the common kite of Europe; unlike that bird, however, it feeds on the wing, seizing in its

flight the larger insects which often crowd the trees in the American forests. In the capture of these, its action is very similar to that of the swallows; but as its size and power are both much greater, it has more dash about it; and a hen, seen on the wing, might perhaps be mistaken for some giant swallow in very different livery from what the rest of the race usually wear; yet the bill, the talons, the feathering of the legs, and the whole appearance of the bird, point clearly at the class to which it belongs. Wilson mentions that its favourite food is a species of lizard, remarkable for the rapid changes of its brilliant colour, and also of the little green snake which feeds upon this lizard. The one pursues the other to the remotest extremities of the twigs; and the kite, which is beating about, captures them both. According to Wilson, "the swallow-tailed hawk measures two feet in length, and upwards of four feet six inches in extent; the bill is black; cere yellow, covered at the base with bristles; iris of the eye silvery cream, surrounded with a blood-red ring; whole head and neck pure white, the shafts fine black hairs; the whole lower parts also pure white; the throat and breast shafted in the same manner; upper parts, or back, black, glossed with green purple; whole lesser coverts very dark purple; wings long, reaching within two inches of the tip of the tail, and black; tail also very long and remarkably forked, consisting of twelve feathers, all black, glossed with green and purple; several of the tertials white, or edged with white, but generally covered with scapulars; inner veins of the secondaries white on the upper half, black towards their points; lining of the wings white; legs yellow, short and thick, and feathered before half way below the knee, claws much curved, whitish; outer claw very small. The greater part of the plumage is white at the base; and, when the scapulars are a little displaced, they appear spotted with white. This was a male of perfect plumage. The colour and markings of the male and female are nearly alike."

There are several other species which have been noticed in different parts of the world, especially in southern Asia, Australia, and America; but they do not appear to differ greatly from the common kite in the more essential parts of their characters, so that very brief notices of them are enough for popular purposes.

GOVINDA KITE (*M. Govinda*). This species is found in the Deccan, and probably in most other parts of India. It has the head, neck, and under part of the body reddish brown, with dusky lines in the centre of the feathers; and the upper part brown, the tail much forked, and marked with obscure bars. It floats much about in the air, and is fully more daring than the European kite. The length of the body is two feet two, and that of the tail eleven.

The wedge-tailed kite is a native of Australia, and the Riocourt's kite is a species of the Cape.

KNIGHTIA (R. Brown). A genus of plants of which only one species is described, and found in New Zealand. It belongs to the fourth class of Linneus, and to the natural order *Proteaceæ*.

KNOWLTONIA (Salisbury). A genus of curious herbaceous plants, natives of the Cape of Good Hope, belonging to *Ranunculaceæ*. They are cultivated in the green-house, and increased by seeds or by dividing the roots. They are allied to and resemble the genus *Adonis*.

KOALA. The pouched bear of the Australians (*Phascolarctos*), but more correctly expressed by its

native name of koala. It is a marsupial animal, and rather peculiar both in its structure and its habits.

Koala.

It is an animal about the size of a middling dog, of very curious expression and formation in some of its parts. Its head is round, terminating in a distinct muzzle, formed for turning up the earth, and having the nostrils, in the point, with entire margins something resembling those in the hog. The eyes are nearly round, the ears a little pointed, covered with long hair, and having the opening turned toward the front. The body is rather clumsy in form according to the accounts, and by no means fitted for quick motion. The fore legs contain five toes on each, which act two against three, namely, the thumb and next one against the remaining ones. The metacarpal bones in those feet are very small, and thus the toes appear to spread out not very unlike those of a bird, to which they have also some resemblance in the shape of the claws, which are sharp and a good deal crooked, but not retractile. The hind feet have no claw upon the thumb, and those on the other toes are smaller than in the fore feet, while the toes themselves have not the opposite action of the fore ones. There are six incisive teeth in the upper jaw, of which the two in the middle are longer than the rest, and there are two in the under jaw. In some of the specimens which have been examined, there have been no canines in either jaw, whereas in others there have been small ones in the upper. There are four grinders with tuberculated crowns on each side of both jaws, and two false ones on each side of the upper one; but they are wanting in the under. The habits of the animal are obscure; but from the structure of its mouth, and its timid nature, it cannot be regarded as carnivorous. Insects, and probably also vegetable matters, form the chief part of its food. It is expert in climbing trees; for which purpose the particular structure of the fore feet, and the sharpness of the claws with which the toes of these are furnished, adapt it very well. It is also said to burrow in the ground, but its feet are by no means well suited for digging; and the probability is, that it takes up its abode in holes which it finds ready prepared. There is no want of such shelters in the woods of Australia, for most species of trees there are prone to get hollow, and very many of the smaller native animals take up their abodes in those hollows. The koala is, as we have said, an animal of mild manners, and the female is attentive to the young one, which it continues to carry about for a

long time after it is brought forth, the young being seated on the shoulders and neck of its parent, where it holds its place very firmly, and lives and reposes there, except when the mother suckles it, until it is strong enough for finding its own food. Not much is known of its disposition and habits, and it seems so peaceable a creature, that there is probably very little to be known. Indeed, all the native mammalia of New Holland, though they are singular, are inferior in the development of their system of sensation to those of every other part of the world, and their resources are so few, that they will gradually disappear as the country becomes more thickly peopled.

KURTUS. A genus of spinous finned fishes, belonging to the family with scaly fins, and occupying a place in the system intermediate between the dorees and the coryphenes. They are surface fishes, included in the very extensive family of the mackerel, which includes many of the fast swimming and richly coloured fishes of the tropical seas. Of the genus under consideration only one species is known, *Kurtus cornutus*, so called from a small curved horn which stands in front of the dorsal fin. The dorsal fins are not very long, but the ventral and anal fins are well produced. The scales over the whole body are so minute, that they cannot be observed upon the dried skin. They are very richly coloured, being silvery of brilliant lustre, with golden spots on the back. The pectoral fins are gold colour with red margins; and the remaining fins are very brilliant sky blue, bordered with yellow or with white. The body is very much compressed, and its cavity is remarkably short. The fish is rare, however, even in the tropical seas; while in those of the temperate countries there is not a specimen. It is not a large fish, never exceeding a foot in length, and generally not much more than six inches. Still it contributes, along with other nearly allied genera, of which the colours are also very brilliant, to give no small degree of interest to the water in the tropical seas; and as the water there is not only clear in most places, but much better illuminated by the more direct light of the sun, the brilliant colours of the fishes are shown off to great advantage as compared with anything which we can witness near our own shores.

KYDIA (Roxburgh). A genus of East India trees, belonging to the class *Monadelphæa*, and to the natural order *Hyttneriaceæ*. It succeeds in our stoves, and is propagated by cuttings.

LABIA (Leach). A genus of dermopterous insects, having for its type the little earwig. See **FORFICULA**.

LABIATÆ. A large natural order, containing a portion of *Diandria Monogynia*, and the whole of *Didynamia Gymnospermia* of Linnæus. The plants of this order are characterised by their didynamous stamens, four little nuts or naked seeds, single style, and irregular corolla. They are mostly natives of extra-tropical countries, although under the form of *Hyptis*, *Anisomeles*, *Leucas*, *Ocimum*, &c.; they are found in the hottest zones of the world. Many are extremely odoriferous in the leaves; some bear handsome flowers; but a great number are only weeds.

This order, by some writers, is called *Menthaceæ*, and the strict adherence to the normal characters of this type must be obvious to every one. Indeed, so striking is their similitude, that Jussieu observed

they might be considered as forming a vast but single genus; and to this uniformity of structure may perhaps be attributed their equally remarkable similitude in properties. None of the *Labiata* are poisonous, nor are any even suspected of being injurious; the betony is the most acrid of the whole. Scarcely any are used as ordinary food, although many form grateful condiments; the stachys and the basil being perhaps the only ones that are esculent as pot herbs. They are all more or less fragrant, most are sweet scented, but some are fetid. Their odours are in general owing to the essential oils which are secreted in abundance, and found in numerous receptacles on their leaves and stalks. M. Fee observes, that odoriferous plants exhibit three remarkable variations. In some the aromatic principle is free, and then it is dissipated by drying; this occurs chiefly in the tuberose and jasmine, and it is not communicable either to water or spirit, and seems to be artificially retained only by the aid of fixed oils; and occasionally, as in the lily and narcissus, it cannot be retained at all. In some, the aromatic principle is in union with, or is peculiar to, the essential oil, with which the utricle or cryptæ are replete; and in this form it is miscible with water and alcohol, but scarcely with fixed oils. In others again, it is in combination with a resin, or gum-resin, and then it may be collected in concrete masses by wounding the plants, or if by distillation, it deposits camphor after standing for some time. The fragrance of the *Labiata* is dependent on an essential oil, or odoriferous principle of the latter kind, and their oil is remarkable for the quantity of camphor it contains.

LABIDURA (Leach). A genus of dermopterous insects, having for its type the gigantic earwig. See **FORFICULA**.

LABIO. A genus of molluscs established by Ocken, but named by Lamarck **MONODONTA**, under which it will be further described.

LABLAB (Adanson). A genus of plants chiefly tropical, some of which are cultivated for their pods and seeds in China, India, and Egypt. They are climbing annuals, and belong to the natural order *Leguminosæ*. This genus formerly belonged to *Dolichos*.

LABROIDEÆ—the Wrasse family. A family of spinous finned fishes, belonging to the grand division which have labyrinths in the bones of the pharynx. They obtain their name from the great enlargement of the lips, which form a sort of roll on each jaw, beyond which the teeth stand obliquely forward; and so remarkable is this character, that if one of the family has been carefully examined for only once, there is never any difficulty in distinguishing the other members of the family. The body is oblong, scaly, with a single dorsal fin, supported by spinous rays in the anterior part, and generally with a transparent membrane. There are three divisions of the pharynx, the two upper ones close on the bones of cranium, and the lower one larger than any of these; but they are always armed with teeth, which are sometimes placed like pavement, and at other times pointed, and on the margins of the laminae. Their gill-lids are toothed, and the gills consist of five rays. The teeth in the jaws are conical, and those of the fore part the longest. The stomach is a simple cul-de-sac, but it joins the intestine without any cæcum. The air bladder is simple and very strong.

They are fish of average size, but very active in

B

their habits, and of that moderately elongated form which we are in the habit of associating with our common notions of a fish. They are found most abundantly on rocky coasts, and are in fact the rock fish properly so called, feeding upon crustacea and mollusca, which the peculiar form of their mouths enables them readily to pull down from the rocks, or otherwise to seize, while their strong teeth enable them to break even hard shells without difficulty.

They are found in the seas of almost every region of the globe, from the Equator to Greenland; but they are far more abundant in the warm seas than even in the temperate; and in the cold seas they are comparatively rare. Their flesh is, generally speaking, agreeable; but their haunts are too peculiar for admitting of their being commonly seen in the fish markets of Britain. They do not frequent the sandy or muddy bays, nor the banks upon which ground fishes congregate, but are confined to the clear water among the rocks; and, therefore, the bold shores of Cornwall are the places of the British seas where they are most frequently met with. The whole of them are dressed in splendid attire; their scales are as splendid as polished metals; and their colours have all the beaming lustre of precious stones when the light falls obliquely upon them. There are many fine species in the Mediterranean; but their grand resort is among the islands which stud the vast expanse of the Pacific; and some of the species which occur there are of extraordinary beauty. They do not all agree in every particular, so that it becomes necessary to divide them into sub-families, or at all events into genera.

We shall briefly mention the distinguishing characters of these genera, as the species are too many for our enumeration; and, having done so, we shall more particularly notice at least the leading ones which frequent the British seas.

First, *Labrus*, properly so called. They have no spines, nor marginal teeth to their gill covers, and no appendages to the tail; the cheeks and gill covers are furnished with scales; the body is oblong, and the lateral line is nearly straight. They are most abundant in the Mediterranean as European fishes; but they are also found as far to the northward as the coast of Norway.

Second, *Julis*, is readily distinguished from the former by having the cheeks and the gill covers with smooth skin, and without any scales; their lateral line is strongly bent upwards, toward the termination of the single dorsal fins. Several species are found in the temperate seas; but there are many more in the Pacific, and there they are remarkable for the richness of their colours. One very beautiful species belonging to this sub-division, occurs in the Mediterranean, the Archipelago, and also the Red Sea, always among the rocks and in clear water, so that the play of their rich colours can be seen to the greatest advantage. The general colour of its body is bright violet, marked along its side by a zig-zag band of brilliant orange, and having the dorsal and anal fins marked with three bands, the first yellow, the second red, and the last blue. It is but a small fish, seldom exceeding six inches in length; but its flesh is excellent, and it is easily taken with hook and line.

Third, *Crenilabrus*. These have the body oblong, with a single dorsal fin, supported anteriorly by very strong spines; and they have the margins of the gill flaps toothed, by which they are distinguished from

the first sub-division; and they resemble that sub-division in the sides of the head, being covered with scales. Several of them are found in the Mediterranean, and some are celebrated for the quality of their flesh.

Fourth, *Coriscus*. These resemble the third division in many of their characters; but they have the mouth a little protrusile. They are of small size, and some of them are met with in the Mediterranean.

Fifth, *Enclinus*, have the head scaly, and the scales of the tail continued in the basis of the rays. The lateral line is interrupted immediately under the dorsal fin. Some doubts remain as to the perfect correctness of this particular division.

Sixth, *Epibulus*. The character of these, by which they are chiefly distinguished from the others, is the form of the mouth, which is capable of being protruded to some length, in the form of a tube, by means of which they contrive to suck or draw into their mouths those small fishes upon which they feed. Some of these have the body shaped not unlike that of the carp, and they grow to the length of nine or ten inches, or sometimes nearly a foot. The lateral line is interrupted in the same manner as in the last specimen.

Seventh, *Gomphosus*, have the head entirely smooth, or without scales, and the muzzle produced into a tube with a small opening; there are but few species known, and these are inhabitants of the Indian seas.

We shall now notice one or two of the British species; because, from the singularity of their lips, and the beauty of their colours, they are interesting.

BALLAM WRASSE (*L. maculatus*). This species, which is not by any means rare on our coasts, is in some places called the old wife, or old woman of the sea, and either the family are of inferior quality in our seas than they are in the Mediterranean, or our taste is different; for the flesh of this wrasse is so soft that the fish is hardly worth taking as a marketable article, the chief demand for it being from collectors and students. It frequents the deep holes among rocks, where it lies in wait among the sea weed, for those crustacea upon which it feeds. It is often a foot and a half in length, and weighs between three and four pounds. The colour varies both seasonally, and as it should seem in different individuals. Generally speaking it is red, passing into yellowish orange on the under part of the body, ornamented with spots of bluish green, and having the fins of the same colour spotted with red. It occurs in many parts of our rocky coasts, both on the east coast of the islands and on the west, but more abundantly on the latter, because it is more rocky. We quote a very accurate description of one, from Yarrell's excellent and accurate Natural History of British Fishes. "The length of the head," says Mr. Yarrell, "compared to the whole length of head, body, and tail, as one to four; the depth of the body alone equal to the length of the head; the lower edge of the scaly portion of the cheek rounded, the scales only half as large as those on the operculum; preoperculum without scales, the horizontal and vertical edges forming an angle somewhat obtuse, the ascending line being oblique, the margin entire; operculum broad, covered with large scales, and ending in a membranous projection over the upper part of the origin of the pectoral fin. The pectoral fin broad and rounded; the membranes connecting the rays of all the fins spotted with verditer, rather inclining to blue than green; the fin rays red-

dish orange, with six or seven scales in succession between each ray of the caudal fin. Back and sides bluish green, paler on the belly; all the scales margined with orange red, the margins varying in breadth in different specimens, and thus producing the prevalence of the blue or orange colour; six rows of scales between the lateral line and the middle portion of the dorsal fin. Head and cheeks bluish green, reticulated with orange red lines; lips flesh colour; about eighteen teeth in each jaw, conical, those in front the longest; the tail slightly rounded at the upper and under corner, the top dusky."

GREEN-STREAKED WRASSE (*L. lineatus*). This species sometimes makes its appearance upon the British shores, but very rarely; it is understood, however, to be the same species which is common in the Mediterranean, and known there by the name of the parrot fish. Its ground colour is a fine grass green, deeper on the back than in any other part, and passing into greenish yellow on the belly. There is a stripe of bright blue passing along each side from the head to the tail; but this is said to be a character of the male only, the female being uniformly green in all the upper part. The fins are also green. The body is rather lengthened, and more oval than the former species. The upper jaw is longer than the lower, and both jaws are furnished with teeth, those in the front being largest. It visits our shores, at least the shore of Cornwall, the only one on which it has hitherto been observed in the summer season; but it is little known even to the fishermen, and is a subject of curiosity rather than of use.

THE BLUE-STRIPED WRASSE (*L. variegatus*), is not so rare upon the British shores as the former, and it is pretty common on the south and east of Ireland. The general colour of the body and head is orange, varying from orange red to orange yellow, palest on the belly, and striped with bright blue on the sides. The eyes are orange and blue; the membrane which connects the first twelve rays of the dorsal fin is blue with an orange margin, and the remaining portion of that fin orange with blue spots; the rest of the fins are orange with blue tips. This one grows to the length of a foot, which is considerably more than the species immediately preceding. Different specimens are subject to considerable varieties of colour, but they are all very beautiful; indeed, in so far as colour is concerned, this is one of the most splendid fishes which occurs in any part of the European seas. In the Mediterranean, where its colours are finer than they are when it ranges into colder latitudes, it is sometimes called the peacock fish.

THE SEA WIFE (*L. vetula*). This species grows to rather more than a foot in length, and it has the caudal fin slightly rounded, though not more so than some of the others. The upper part of the back, the neck, and the sides, are blue of an intense colour, and sometimes passing into blackish purple on the middle of the back. It is marked also with bright orange, and the head has a tinge of flesh colour more or less intense. The irides are blue, and so also are all the fins, with the exception of the tips of the ventrals, which are black. This fish is described by some of the continental naturalists as being common on the coast of France, and ranging as far north as Norway; but if this be correct it must pass round the western side of Britain, as it is exceedingly rare on the British shores; and the opposite shores of the Netherlands and Germany are not suited to its habits.

THE RED WRASSE (*L. cornus*). This species occurs on many parts of the British coasts, and also on those of Norway and in the Baltic. The usual colours are fine orange red on the upper part, passing into pale orange on the under. A portion of the spinous part of the dorsal fin is rich purple, and two spots on the posterior part of the same fin, and a third one nearer the tail, are very deep purple. Four spots of very delicate rose-colour alternate with those three dark purple ones, and give a very striking character to the upper part of the fish, from the middle of the dorsal fin backwards. Its habits do not appear to differ in any important particular from those of the rest of the genus. Such are a few of those which occasionally occur on the British shores.

LABURNUM, is the *Cytisus laburnum* of Linnaeus, one of the most beautiful and conspicuous flowering trees in this or any other country. It is said to be a native of Switzerland, and was introduced into this country as far back as 1596. It is scarcely necessary to add that it belongs to *Leguminosae*.

LAC INSECT. A small annulose animal, inhabiting the East Indies, belonging to the genus *Chermes*, of which the female is large, unwieldy, and destitute of wings; and the male small, provided with two wings, and a pair of slender filaments arising from the extremity of the abdomen. It derives its specific name, *Chermes Lacca*, from the substance called lac, which is found upon several trees and shrubs in the East Indies, and which is of considerable use in various manufactures, being employed in its manufactured state in the making of sealing wax, varnishes, &c.; it is also the basis of the French polish, and is used in manufacturing waterproof hats. Dr. Roxburgh has published a detailed account of this insect and its production, in the Philosophical Transactions of the Royal Society. "Some pieces of very fresh-looking lac," observes this author, "adhering to small branches of *mimosa cinerea*, were brought to me from the mountains. I kept them carefully in wide-mouthed bottles, slightly covered; and fourteen days from the time they came from the hills thousands of exceedingly minute red animals were observed crawling about the lac and the branches it adhered to, and still more were issuing from small holes on the surface of the cells. By the assistance of glasses small excrescences were also observed interspersed among these holes, two regularly to each hole, crowned with some very fine white hairs, which being wiped off, two white spots appeared. The animals, when single, ran about pretty briskly; but in general, on opening the cells, they were so numerous as to be crowded over one another. The substance of which the cells were formed cannot be better described, with respect to appearance, than by saying that it is like the transparent amber of which beads are made. The external covering of the cells is about the twenty-fourth part of an inch in thickness, it is remarkably strong and able to resist injuries; the partitions are much thinner. The cells are in general irregular squares, pentagons, and hexagons, about an eighth of an inch in diameter, and a quarter of an inch deep; they have no communication with each other. All those opened during the time the animals were issuing from them, contained on one side, which occupied half the cell, a small bag, filled with a thick jelly-like red liquor, replete with what I take to be the eggs. These bags adhere to the bottom of the cells, and have each two necks, which pass through holes in

the outward coat of the cells, forming the excrescences we have mentioned, ending in some fine hairs. The other half of the cells have a distinct opening, and contain a white substance, like a few filaments of cotton rolled together, and a number of the little red insects themselves crawling about ready to make their exit. Their portion of each cell is about one half, and I think must have contained nearly one hundred of these animals. In other cells less forward I found a thick red dark blood-coloured liquor, with numbers of exceedingly minute eggs, many times smaller than those found in the small bags which occupied the other half of the cells." In the preceding account it is evident, from the close relationship existing between the lac insect and the common species of coccus of our own country, that the cells above described were in reality the female insects, whose bodies serve as a covering for the eggs in our species, which are enveloped in a kind of cottony secretion, in the midst of which the young insects just hatched may occasionally be found, and the "minute red animals" were unquestionably the larvæ of the lac insect, of which the development of the males, furnished with wings, &c., is perfectly analogous to that of the coccus adonidum; whilst, on the other hand, the female, as it advances in age, loses its activity, and becomes a shapeless mass. We give this explanation, although Roxburgh has shown the transformations of what he terms the female, but which we do not hesitate to state is the male insect; and this is the more important, because the male insects contribute in no degree to the producing the material called lac.

Lac is known as an article of commerce under three distinct names: stick lac, which is the original state in which it is found adhering to the twigs; seed lac, from which the red colour has been extracted, by immersion in water; and shell lac, which is produced by melting the seed lac, and straining it through cotton bags over a charcoal fire, and then spreading it out into thin plates. The red colour extracted, when the stick lac is made into seed lac, is employed in dyeing; it is less brilliant than cochineal, but more durable.

A curious use is made of this material in India, by forming it into grinding stones, in the following manner: "Take of river sand three parts, and of seed lac washed one part, mix them over a fire, and form the mass into the shape of a grindstone, having a square hole in the centre, cement it to an axis with melted lac, heat the stone moderately, and while revolving rapidly on its axis it can be easily formed into a circle." Polishing grindstones are also formed by mixing two parts of sand, passed through fine muslin, with one of lac; these cut very fast. The same composition is formed upon sticks, for cutting stones, shells, &c. by the hand.

LACHENALIA (Jacquin). A genus of beautiful bulbous plants, natives of the Cape of Good Hope. The flowers are hexandrous, and the genus stands in the order *Asphodeleæ*. Generic character:—calyx of six petals, bell-shaped; exterior petals shorter than the outer, often callous at the point; stamens joined to the base of the petals; filaments awl-shaped; anthers oblong; style awl-shaped; seed-vessel three-sided, three-celled, and full of seeds. The *Lachena-lia* are green-house plants, thriving in sandy loam and leaf, or moor-earth, requiring no water when dormant, but a due quantity while growing. They may be increased by offsets or seeds.

LACTUCA (Linnæus). A genus of annual and biennial herbs, many of which are eminently useful

as salad and culinary plants. They belong to *Compositæ*. The very many varieties of lettuce now cultivated in our gardens, shows the genus has been long in cultivation. Indeed the annals of botany give no certain account either of its introduction into Britain, or of what country the best sort is a native. The *Lactuca* was known to Pliny, and no doubt was brought to this country by that author's countrymen.

Nothing can be easier than the cultivation of this salad herb. There is certainly some skill required in having a constant supply throughout the year, because the summer-sown plants are not hardy enough to stand the frosts of winter, and therefore require to be kept in glass frames; but all the spring sowings come to great perfection, if the ground on which they are sown or planted be moist and rich. It is good management to sow a little seed in every month of the year, whence supplies of plants are drawn for transplanting at every favourable season. For the earliest spring crops, the seed should be sown under glass in the autumn; and when the seedlings are large enough, they are dibbed out on well-prepared ground as soon in the spring as the state of the weather will permit. Successive sowings and transplantings continue the supply throughout the summer and autumn months.

Cabbage lettuce is much required in French cooking; and to obtain this in the winter, it is raised on hot-beds. For this purpose, the seeds of the largest growing white kinds are sown on a warm border in August and September. Substantial hot-beds are made soon after, covered with a frame and lights, and a good thickness of rich compost. On this lettuce plants are put at one foot distance from each other, and as near the glass as possible. Here the plants spread and grow luxuriantly; and by the time the bed gets too cold, the lettuce is all used; other beds being made in the meantime, continue the supply. The upright growing sorts, fit for salads, are called *coss*, and those for stewing are called *cabbage* lettuce.

LADY-BIRD. The common English name for a pretty little coleopterous insect, known systematically under the name of *Coccinella septem-punctata*, Linnæus. See COCCINELLIDÆ.

LÆMODIPODA (Latreille). A singular order of crustaceous animals, belonging to the second subsection *Edriophthalma* (or those with eyes not placed upon foot-stalks) of the hard-shelled section (*Mala-costraca*). These curious insects are of small size, and have the body in general narrow, elongated, or linear, composed of eight or nine joints, with the abdomen rudimental and furnished with several small anal appendages. They have four simple setaceous antennæ arising from a three-jointed foot-stalk, the mandibles are not furnished with palpi, the legs terminated by a strong hook, except the third and fourth pairs in some species, which are nearly rudimental. Unlike the other *Edriophthalma*, however, they appear to respire by means of several vesicles placed at the base of the four pairs of legs, commencing with the second or third pair, including those of the head, which latter represent the four anterior foot-jaws greatly developed. No other respiratory organs have been observed. The females, at least in the genus *Cyamus*, carry their eggs beneath the second and third segments of the body, in a kind of pouch formed of approximating scales. They are all marine; according to Savigny, they approach the *Pycnogonides*, and thus lead the way from the *Crustacea* to the *Arachnides*.

The order is divisible into two families.

1. *Cyamida* (*Ovalia*, Latreille). Having the body oval, with transverse segments, and containing the single genus *CYAMUS*, which see; and
2. *Caprellida* (*Filiformia*, Latreille). Having the body long and slender, and the segments longitudinal. See *CAPRELLIDÆ*.

LAGENARIA (Schreber). A genus of creeping annuals, natives of India, called, from the shape of the fruit, the "bottle gourd." They belong to the natural order *Cucurbitaceæ*, and of course are closely allied to the common gourds, melons, cucumbers, &c. The shells of the fruit are converted into many kinds of vessels for domestic uses. They may be raised on hot-beds, in this country, as a curiosity, if required.

LAGERSTRÆMIA (Linnæus). A genus of beautiful flowering shrubs, natives of India. Class and order *Polyandria Monogynia*, and natural order *Salicariæ*. Generic character:—calyx in six divisions, with two bractea at the base; lobes distinctly sinuated; petals six, and clawed, inserted into the throat of the calyx; stamens inserted into the tube of the calyx; filaments filiform; anthers oval and incumbent; capsule surrounded by the calyx, three to six-valved, three to six celled, containing winged seeds. This, the *L. Indica*, is one of the most ornamental shrubs of its native country. They flower frequently in our stoves, though but feebly. They, however, flower beautifully if planted in the open air, against a south wall, and securely defended against the frost of winter. They are increased by cuttings.

LAGRIA (Fabricius). A genus of coleopterous insects, belonging to the section *Heteromera*, subsection *Trachelides*, and family *Melandyridæ*, of Leach, but forming, according to Latreille, the type of a distinct tribe, *Lagriariæ*, having the body elongated, narrowed in front, with the thorax sub-cylindric or square, the antennæ simple, filiform, or gradually thickened, and inserted in a notch in the eyes, with the last joint longer than the preceding, especially in the males, the tibiæ narrow, and the fourth joint of the tarsi bilobed; the body is soft, and the elytra flexible. They reside in hedges and woods, and counterfeit death on being touched. There is only a single British species, *Lagria hirta*, which is very common in the early summer months.

LAMBERTIA (Smith). A genus of New Holland evergreen shrubs, named in honour of A. B. Lambert, Esq., V. P. Lin. Soc. of London. They belong to the fourth class of Linnæus, and to the natural order *Proteaceæ*. Generic character:—involucre coloured, one to seven-flowered; receptacle plain and naked; calyx tubular and four-cleft; stamens inserted in the clefts; four scales below the germen, either distinct or united; stigma awl-shaped; folliculus one-celled; seeds margined. The *Lambertias* are treated as green-house plants, potted in light sandy loam and moor-earth, are impatient of too much water, and may be propagated by cuttings planted in sand.

LAMELLIBRANCHIATA. De Blainville's third order of the third class of malacology. The molluscs constituting this order are formed, in many respects, similar to the *Accephalophora*; but their branchiæ are shaped like large semicircular leaves symmetrically disposed on both sides of the animal's body; two pairs on either; their position is between the abdomen and the mantle; the mouth is large, and

transversely placed between two lips, terminated by sub-branchial appendages.

The shell of these animals invariably consists of two parts or valves placed on either side of the body, lying more or less upon each other, and closed or opened by means of a ligament and adductor muscles.

LAMELLICORNES (Latreille). A very extensive tribe or subsection of coleopterous insects, belonging to the section *Pentamera*, and corresponding with the Linnæan genera *Scarabæus* and *Lucanus*. In this group, which was placed by Linnæus and Fabricius at the head of the insect tribes, are comprised some of the most gigantic species, such as the hercules and elephant beetles. The various species figured in our plate of *BETLES*, together with the cockchafer, rosechafer, shardborne beetle, and a vast number of others to which no ordinary names have been assigned, are also lamellicorn beetles—a term indicating the principal character of the subsection, derived from the structure of the antennæ, which are always short, composed of nine or ten joints, and always terminated by a club generally formed of the three last joints, which are in the form of narrow plates laid one against another like the leaves of a book, capable of opening to a considerable width; sometimes, however, the joints of the club of the antennæ are much more numerous; and in others the outer plates of the club are so shaped that they form a sort of box, within which the central plate is shut up. These organs are inserted in a deep excavation beneath the lateral margins of the head. The body is generally ovoid, oval, or rounded; the outer edge of the anterior tibiæ is toothed; and the joints of the tarsi, except in some males, are entire, and unprovided with cushions on the under surface; the interior part of the head is often produced into a shield over the mouth; and the mentum is occasionally very large, entirely closing the mouth from beneath. The mandibles, in certain of the dung-feeding species, offer a peculiarity not to be observed in any other coleopterous insects, that of being membranous. The males generally differ very greatly from their partners in the extraordinary horns with which the head and thorax are often provided, of which some examples will be seen in our plate of *BETLES*, and in our article *DYNASTES*, wherein the figure of *D. hercules* has accidentally been turned with the back downwards. It is a curious circumstance, that these cornuted male insects are generally of a much larger size than the females, whereas in the generality of insects the contrary is the case.

As regards their size, the singularity of their forms, and the brilliancy of colour of many of the species, they are amongst the most conspicuous of the beetles. It is, however, only to those species which feed upon living vegetable substances in their final state that the last remark may be applied, since many of the species which feed upon vegetable matter in a state of decomposition, and especially such as frequent the excrement of animals, are generally of a dark brown or black colour. Some exotic coprophagous species are, however, as splendidly coloured as the phyllophagous species. From the large size of many of these species, and especially of those inhabiting tropical climates, it must be evident that they must be eminently serviceable in clearing away decomposing vegetable matter, in which the larvæ in general reside. These larvæ are thick fleshy grubs, having the body long, semicylindric, transversely rugose, of a dirty white colour, with the head armed with powerful jaws

for biting, and other parts of the mouth and two antennæ. The body is composed of twelve rings, of which the last is the largest, and to the first three of which six scaly legs are attached; each side the body is furnished with nine spiracles; the extremity of the body is rounded and generally curved towards the breast, so that the back being convex or arched, the larvæ cannot conveniently stretch themselves in a straight direction; they consequently crawl but badly, constantly tumbling to one side or the other; but the legs of these larvæ are not walking legs, neither do their habits and localities require any such powers; so that the apparently awkward form of the body is seen, when these are taken into consideration, to be not so unnatural as was at first supposed. They feed upon dung, manure, rotting bark, the roots of vegetables, &c., so that being in the midst of their food, powerful locomotive organs would be useless. Still legs are needed in order to enable the larvæ to make their way through the food. An idea may be obtained of the general form of these grubs from the figure of the preparatory stages of *Cetonia*, given in the article *CETONIIDÆ*, or that of the larva of *Trichius*, figured in the article *INSECT*; sometimes, as is the case with the larva of the cockchaffer, considerable damage is produced by their ravages. In some species the larva state extends for three or four years, at the expiration of which they form, in their retreats, an oval or elongate cocoon, composed of earth or the remains of the materials which they have devoured, and which they agglomerate together with a secretion which they emit for that purpose.

The nervous system of these insects, as considered in the larva and imago states, is subject to very remarkable variations, the ganglions being less numerous, or rather the greater number being confluent in the perfect state; the two posterior emitting a great number of elongated filaments, disposed like rays. The digestive system, as in all herbivorous insects, is considerably elongated.

In the new edition of Dejean's Catalogue, we find 2060 species of lamellicorn insects noticed; of this number, scarcely more than a twentieth part occur in this country, and of these the majority are of small size; but in our native list are to be mentioned the cockchaffer and stag-beetle, two of our largest coleopterous insects. But those are comparatively of small size, when placed in contrast with some of the exotic species. This group of insects has formed the subject of a most elaborate treatise by Mr. MacLeay, forming a portion of the *Horæ Entomologicæ*, by whom the intimate relation of the *Histeridæ* with the *Lucanidæ* (*Recticera*, *Thalerothaga*, MacLeay) was proved, and by whom the *Petalocera*, or that portion of the lamellicorn beetles corresponding with the Linnæan genus *Scarabæus*, was divided and arranged as follows.

Petalocera.

By this diagram, which in some degree illustrates the quinary views and theory of Mr. MacLeay, it will be seen that the *Petalocera* are divisible into two groups, named *Thalerothaga* and *Saperophaga*, from the difference in their habits, the former feeding upon leaves and the latter upon moist decaying vegetable matter; that each of these two groups is divisible into five families; that these five families are allied together in such manner that they form a circle; and that the opposite families in each circle offer certain resemblances of analogy not only from the general form of the species, but also from the structure of the mouth, and consequently in the manner of living.

The following are the characters of the ten families into which Mr. MacLeay divides the Linnæan *Scarabæi*, with their corresponding groups according to Latreille. We shall defer our observations upon the lucanideous portion of the *Lamellicornes*, until we arrive at the article *LUCANUS*.

PETALOCERA, Dumeril; **SCARABÆUS**, Linnæus; antennæ not elbowed, with a lamellate club; mandibles generally concealed.

A. *Saperophaga*.—Legs strong, the posterior pair remote, tibiae broad, elytra often covering the anus.

* *Coprophagi*, dung feeders; maxillæ with membranous lobes, and therefore living upon juices, and as it were by licking their food.

1. *Geotrupidæ*, MacLeay (*Arenicoles geotrupidæ*, Latreille); mandibles corneous porrected; feed upon moist excrement; reside under dung or in boleti; digging under ground.

2. *Scarabæidæ*, MacLeay (*Coprophagi scarabæidæ*, p. Latreille); mandibles membranous, concealed under the clypeus, palpi hairy with the last joint small; feed upon moist excrement; reside in dung; fly in the twilight.

3. *Aphodidæ*, MacLeay (*Coprophagi scarabæidæ*, p. Latreille); mandibles membranous, concealed, palpi naked with equal sized joints; feed upon moist excrement; reside in dung; fly in the sunshine.

** *Xerophaga*, feeders upon rotten vegetable matter; maxillæ horny, and therefore live on a more solid species of food, and by mastication.

4. *Trogidæ*, MacLeay (*Arenicoles trogidæ*, Latreille); maxillæ with two lobes, and a corneous curved tooth, anus covered; live in sandy places; feed on putrid matters.

5. *Dynastidæ*, MacLeay (*Xylophili*, p. Latreille); maxillæ dentate or unarmed, with one lobe, anus naked; feed on wood; reside in rotten wood, or under bark.

B. *Thalerothaga*, legs more slender, tibiae narrower, elytra seldom covering the anus.

* *Phyllophaga*, leaf-eaters; maxillæ corneous.

6. *Anoplognathidæ*, MacLeay (*Phyllophagi*, p. Latreille); maxillæ dentate or unarmed, labrum triangular.

7. *Melolonthidæ*, MacLeay (*Phyllophagi* †, p. Latreille); maxillæ dentate; labrum linear or emarginate.

† There is an evident error relative to this group in the *Règne Animal*, second edition, vol. iv. p. 588, line 1, where the *Melolonthidæ* are referred to the *Xylophili* instead of the *Phyllophagi*.

*• *Anthobii*, feeding on sap or the nectar of flowers; maxillæ with membranous lobes.

8. *Glaphyridæ*, MacLeay (*Anthobii*, Latreille); mandibles concealed under the clypeus, corneous, labrum exserted; probably biting the petals of flowers.

9. *Cetonadæ*, MacLeay (*Melitophili*, Latreille); mandibles concealed under the clypeus, membranous; labrum covered by the clypeus; sap or honey feeders.

10. *Rutelidæ*, MacLeay (*Xylophili*, p. Latreille); mandibles porrected, corneous; habits unknown.

LAMIA (Fabricius). A very extensive and handsome genus, or rather sub-family, of coleopterous insects belonging to the section *Tetramera*, and sub-section *Longicornes* (*Cerambyx*, Linn.), having the labrum visible, extending across the entire breadth of the head; the jaws of moderate size, and alike in both sexes; the outer lobe of the maxillæ narrowed at the tip, and bent over the internal lobe; the eyes always notched and the head always vertical, with the face flattened. Latreille and Serville introduce into this sub-family, which they named *Lamiaria*, the genus *Saperda*, and many Fabrician *Stenocorus*. And in the *Annales de la Société Entomologique de France*, for 1835, is given an entire revision of the whole sub-family, wherein no less than fifty-three generic groups are described. So little is, however, known or described by authors beyond merely structural details, that it would be useless to give a list of the names of these groups without their characters, and these latter would not enter into the plan of our work: we must therefore refer to our article *CERAMBYX*, wherein we have treated of these insects with reference to their more general characters and habits in conjunction with the *Cerambycidæ*.

LAMIUM (Linnæus). A genus of European annual and perennial herbs, commonly called archangel. The flowers are didynamous, and belong to the *Labiata*. A few of the annual species are admitted into the flower garden, but the generality are worthless weeds.

LAMPADIA. A genus of molluscs established by de Montfort and now united to that of *Lenticulina*. They are microscopic shells, and from that cause frequently undiscovered.

LAMPREY (*Petromyzon*, that is, stone-sucker, from the habit of the fish in attaching itself to stones by means of its mouth). A genus of cartilaginous fishes with fixed gills, of which the following are the leading characters. There are seven gill openings on each side, on which account the lamprey is sometimes vulgarly designated the "nine eyed eel." The skin on the upper and under part of the body is elevated or produced into a sort of ridge, which to a certain extent serves the purpose of a fin; but it has little or nothing of the structure of a true fin, there being scarcely any traceable fibres in it; to say nothing of regular rays such as those which are found in the fins of more characteristic fishes; but that very flexibility of the skeleton, arising from the absence of salts of lime to which the absence of distinct bones and jointed articulations is owing, contains in itself a good deal of compensating power, by enabling the animal to bend its body readily, and thus turn the successive flexures into which it is bent into a means of progressive motion through the water, which, though not so rapid as that of those fishes which gain

a momentum at once, is far less fatiguing in the performance. It is highly probable too that the breathing by means of fixed gills is a much less laborious operation than breathing with gills which are free, and which require the constant use of a complicated muscular apparatus. The particular mode of breathing in the lamprey, and indeed in the whole family *Cyclostomus*, "round mouth"—that is, having the mouth formed into a real sucker, by means of which the animals can adhere to that on which they feed, and feed at the same time—is not very well understood in the whole of its details; for though it is not probable that the respiration is suspended always when the animal thus adheres, yet it is not easy to see how a circulation of water, so as to bathe the branchial appendages in the walls of the cells, can be carried on. Lampreys, however, live both in the sea and the fresh waters, and are very tenacious of life. There are one or two species, and probably there may be more of fishes which are so obscure in many of their habits.

THE LAMPREY, OR SEA LAMPREY (*P. marinus*), is found in the seas of all the temperate parts of the northern hemisphere, and to a considerable distance eastward in the Mediterranean; but it does not reach the seas of the Greek peninsula. Whether the current of cold water which sets southward from the Black Sea, and which, during the melting of the snow on the southern Alps is also rolled down in great volume by the Po, may prevent the appearance in those seas of a fish whose sense of temperature is understood to be delicate, it is not easy to say; and, indeed, the physical causes of the geographical distribution of fishes are matters of which we know but little. It is found on the shores of Spain, France, and England, and those of Europe as far north as Norway. It is also found on the opposite shores of America, and in the northern part of the Pacific. The lamprey grows to the length of at least three feet. Its motion very much resembles that of a serpent, only it is more in the horizontal plane, and the body of the fish is remarkably light and flexible. The skin is soft and covered with a viscid secretion, and by many the flesh is highly esteemed. Those who are most recherche in this fish, and it has been a favourite with epicures for a very long time, consider it as in highest condition when the fish begins to ascend the rivers for the purpose of depositing its eggs. The Romans, during the progress of that excessive and unphilosophical luxury which ended in their downfall, were particularly fond of this fish; and in the spring, when it was first found in the mouths of the rivers, a lamprey of moderate size used to sell in Rome for ten pieces of gold. The skeleton of the lamprey, which is a very rudimental cartilaginous imitation of a vertebral column, shows some remarkable seasonal changes. When the animal begins to ascend the rivers, it is so gelatinous and soft as to be hardly distinguishable; but when the lamprey has been for some time in the fresh water, the skeleton becomes a much more firm cartilage, and loses the transparency which it had at the first, when at the same time the flesh has degenerated very much in quality.

THE RIVER LAMPREY (*P. fluviatilis*), is a smaller species than the former and abounds in the fresh-water lakes and rivers of the northern countries; though it is not very clearly ascertained whether it in every situation migrates between the fresh waters

and the sea; that it does so in many instances is certain, and the probability is, that it may do so in all. It is therefore scarcely correct to call the one the sea lamprey, and the other the river one, because both visit the rivers and the sea alternately. The larger one is marbled with brown, yellow, and black; and the smaller one is bluish on the upper part and silvery below; and while the first grows to the length of three feet, the other is rarely found measuring twenty inches in length. They both ascend the rivers about the same time, however, only the smaller one resorts to smaller streams, so that it is much more frequently seen than the large one, and seen in fresh water. The time of their ascending varies of course with the latitude, the season, and the character of the water which the river discharges at the time. But it is always in the early part of the year, that is, about March or April; and as there are many rivers which are full of snow water at such seasons, it is highly probable that this coldness of the water may be one of the reasons why the larger one especially does not ascend them. They return again to the sea about midsummer; and on their descent, and for some time previous to it, they are not sought after as food, and, indeed, they are not wholesome. After they betake themselves to the sea, their manners there are very little known, because there is little inducement to seek after them until they return to the fresh water the next season.

The mouth of the lamprey, whether of the larger or the smaller kind, is a curious structure. The sucker by which it adheres, consists of a border outside the lips, representing on its outer circumference a row of conical papillæ, and within them several rows of smaller fibres. This forms a perfect adhesion to the surface, without interfering with the action of the parts within, which compose the mouth, properly so called. Those parts consist of the true lips, which are the real sucker, for the external part only adheres, but draws no nourishment. Besides the lips, there is an abundant provision of teeth; two of them are fast, the upper one having two points, and the lower one seven, and it is probable that these are the instruments by which it first wounds the animal on which it feeds. There are other teeth, however, which are moveable and smaller than these, and there are minute teeth even upon the tongue; so that the mouth is well armed, and can tear and grind down a pretty strong substance, so as to extract the nutritious matter that it may contain. What the lamprey does chiefly eat is not accurately known, but there does not appear to be much truth in the accounts which are given of its fastening upon the legs and feet of horses and cattle when they are fording the rivers. Its food must, however, be some succulent substance, because its digestive organs are remarkably simple; and though, we cannot state it as an absolute fact, that simplicity in an organ is an invariable sign, that that organ has an easy task to perform, yet it is so in many cases. There is still a smaller river lamprey, which does not exceed eight or ten inches in length; but as it resembles the last mentioned one in colour and in manners, and frequents the same places, it is probable that it may be only the other in an early stage of its growth, and not a separate species.

The *Lampern*, or pride, has been already noticed in the article *AMMOCETES*, so that it is unnecessary to make any particular reference to it here, though it is closely allied to the more typical lampreys. It is, however, more exclusively a river fish, and more of a

mud fish than the lamprey; but it is not thicker than the barrel of a goose quill, and only five inches in length; it stands accused, however, of sucking the blood of other fishes by adhering to their gills, and though the fact is not by any means clearly made out, it is certainly not impossible. Reprisals are made, however, upon the lampern, not by the fishes of course, but by the fishermen, who eagerly seek for them as bait for their hooks; and as the fishes in the very places where they are supposed to commit their depredations, take them more readily than almost any other bait, it is not very probable that they could reach the gills of the same fishes, so as to do serious injury while the fishes remained at freedom to watch over and protect their own interests.

It is certain, however, that the *HAG* (*Myzine*), which is a still softer animal than the lampern, contrives to enter the mouths of fishes while fast on the lines, and extracts their substance by sucking, so as to reduce the fish to little better than an empty skin; but the hag inhabits the sea, and swims in the free water over the fishing banks, while the lampern is rarely found out of the mud and sludge at the bottoms of the rivers. It is said that it is found only in the waters of certain clay formations which are peculiar, and which contain a vast deal of the remains of the shells of mollusca; but whether the clay may have a power of retaining the nutritious substance of the inhabitants of those shells, is a matter not easily ascertained. It is possible that there may be some quality of this kind; for travellers not unworthy of credit mention tribes of the natives of South America who subsist upon clay, and scarcely any thing else, for a longer period of every season than they could possibly exist without food.

LAMPRIAS (Bonelli). A pretty genus of carabideous beetles, belonging to the sub-family, *Brachinides*, and distinguished by their bright and contrasted colours; they are of small size, and reside in hedges.

LAMPYRIDÆ (Leach). A family of coleopterous insects belonging to the section *Pentamera* and sub-section *Serricornes*, having the body oblong and depressed, and of a soft consistence; the antennæ rather short and serrated; the palpi thickened at the tips; the thorax semicircular, or nearly square, concealing the head; the mandibles small, acute, and curved, and the penultimate joint of the tarsi bilobed. This family has for its type the common glow-worm, of which we have already given full details in its alphabetical place.

M. Laporte has lately published an elaborate revision of this extensive family in the *Annales* of the Entomological Society of France, in which he has proposed many new genera. He, however, restricts the family to the true glow-worms, which have the antennæ inserted close together at the base, the head not produced into a snout, and concealed by the thorax, and the eyes of the males are very large, and which possess luminous powers. The typical genus, *Lampyrus*, is distinguished by the apterous condition of the females. Latreille, however, introduces into the family several other groups, namely, *Lycus*, and some other genera having the head exposed and produced into a deflexed snout, and both sexes possessing wings; *Drilus*, having the antennæ widely separated at the base, the head not rostrated, the eyes of moderate size in both sexes, and the females wingless; and *Telephorus* and several other genera, having the antennæ widely apart at the base, the

head not rostrated, the eyes of moderate size; the females winged, and the maxillary palpi but little longer than the labial. The last-named insects are commonly called soldiers and sailors by children.

LANIOGERUS. A genus of naked molluscs established by De Blainville from a specimen existing in the British Museum.

LANISTA. A genus of molluscs so named by De Montfort, but united with the genus *Ampullaria* by modern authors.

LANIUS—shrike, or butcher-bird. A genus of insectivorous birds, belonging to Cuvier's denti-rostral order of the great family *Passeres*, and taking the lead in that order as being the nearest to the birds of prey; and though, generally speaking, insectivorous in their feeding, yet occasionally preying upon smaller birds, which they kill by striking on the head or pinching the neck, and afterwards they hew open the skull and devour the brain of their victim. The general characters are: the bill stout, very much compressed, of mean length, straight in the basal part, but curved toward the tip of the upper mandible, and furnished with a decided tooth; the base of the upper mandible beset with stiff hairs, which are pointed forward; and the under mandible straight, and having a notch answering to the tooth of the upper one. The bill is thus decidedly a carnivorous bill, although it differs from the bills of the diurnal birds of prey in not being curved from the base. The nostrils are placed laterally at the base of the bill, round in their form, and half closed by an arched membrane. The feet have four toes, entirely divided, or free to their bases, three turned to the front and one to the rear, the middle toe being shorter than the tarsus. The first quill of the wing is of moderate length, and the second shorter than the third and fourth, which are the longest. The wing is thus rounded in its termination, and consequently much better adapted for ascent and descent, or short and vigorous flight, than for continuous motion through the air. This agrees with the habit, which is that of subsisting on the largest insects, such as those beetles which in the perfect state are so injurious to the leaves of trees, and of which the larvæ, as inhabiting the earth for more than one year, are peculiarly destructive of the roots of the greens, and sometimes in the absence of those birds, which Providence has set over them to regulate their numbers, completely destroy the grass on the meadows, and the crops of corn in the fields. The shrikes do not attack the larvæ; for they are not, in any sense of the word, ground feeders: but they are exceedingly vigilant in attacking and destroying the full grown insects; and in doing this, they are perhaps of more service to the cultivator than the rook, which is the grand enemy of the larvæ. The shrikes are found about hedges and coppices, where they fly low, and hawk upon the wing for their food; and some of them, at least, have the habit of sticking upon the thorns the bodies of many of those insects which they capture, probably for the purpose of returning to eat them at their leisure. They seldom, if ever, attack birds larger than themselves, or any birds, indeed, which are in vigorous health at the time; but they are very prone to make prey of sick birds, and also of young ones. They have, in fact, the same sanguinary disposition as the regular birds of prey, only they are not so strong, or so powerfully armed. They are exceedingly courageous, and pursue their prey with most persevering industry. As is the case

with predatory birds generally, the pairs evince great attachment for each other, and the parent birds equal attachment for the family. When the young are in want of food, the old birds are more than usually rapacious, and will attack young rabbits, which they despatch by striking on the posterior part of the skull with their bills, and then carry them to the nest. They prefer, however, the insect prey already alluded to; and the places which they frequent are marked by the exuviae of the larger insects stuck upon the thorns of the hedges. Their flight is rapid, but very irregular, consisting of a succession of leaps. They live in families; and their cries to one another are shrill and piercing, though many of them have softer notes when they are flying singly in pursuit of their prey. Their nests are generally made in trees, the external fabric being neatly constructed of withered stems and fibres, and the interior lined with wool and other soft matters. There are a great many species enumerated by writers on ornithology; but the line of distinction between them and the thrush family, which they resemble in many respects, though they differ from them in others, is not very clearly drawn. We must content ourselves with noticing a few of the more remarkable.

GREAT ASH-COLOURED SHRIKE (*L. excubitor*). This bird, from the number of names which it has acquired, must have drawn very considerable attention. It is called the grey shrike, the great butcher bird, the murdering bird, the French pie, and a number of other names; while the Americans, in some places, call it the nine killer, and in others white whisky John; the first name having allusion to the number of prey that it seizes, and fastens on the hedges before it eats any; and the second to the rapid and whisking nature of its flight. This species is ash and grey on the upper part, white on the under; the tail, except the side feathers, which are white, is of a black colour, as is also the eye streak. The colours are, however, subject to very considerable variations; for some are found almost entirely white, and others are of all shades between the common ash and grey, and a white colour. The female, which is of the same size with the male, retains one of the external characters of the birds of prey, at least in part; for the dull white on the under part is, in that sex, marked with semi-circular lines of a dusky colour, not unlike the markings on the under part of some of the hawks. The bill is of a black colour, very strong, considerably hooked at the tip, and having the notch or tooth very prominent. The gape, and over the nostrils, is beset with stiff bristles; but there is not even a rudiment of that cere which is characteristic of the true predatory birds. The tail is even at the end, and consists of twelve feathers. The legs and feet are black; and the irides are of a dusky colour. The length, both of the male and female, is about ten inches; and the extent of the wings is about fourteen.

The singular habit which this species of shrike, more than any of the others, has of sticking the remains of its prey, and sometimes the entire prey, upon the hedges, has given rise to curious conjectures, the most probable of which is, that they do so to attract other prey; for when the trophies of its former doing are thus exhibited upon the hedge, the shrike itself may often be observed beating about until some smaller bird comes to peck at the trophy; and then the shrike drops down, bears it to the ground, instantly dislocates its neck by the gripe of

the mandibles, and very speedily hews open the skull and devours the contents.

In Britain this species occurs only as a straggler; but it is very common in many parts of the European continent, and also of America. In the colder ones it is a migrant retiring in the winter, because there is no food for it; but in places where the summer is hot in proportion, and there are marshy grounds, and consequently many of the larger insects, it is very plentiful in the summer. In Russia, for instance, it occurs in great numbers during the summer, but disappears entirely before the severity of the winter sets in. It is found all the year over in France, where, in summer it haunts the forests, and in winter it resides in the valleys, and even approaches the precincts of human habitations. It chooses either the branchings or forkings of trees in thorny hedges as the situation for its nest, the frame work of which is formed of small twigs twisted and interwoven together with fibrous roots and moss. The nest is so compactly formed, that it is rendered almost impervious to the weather, and it is lined with wool, down, or other soft substance. The eggs vary from four to eight in number; they do not seem to be uniform in their colour; for they have been described by different naturalists as being variously marked. The parent birds of this species manifest a strong affection for their young, and exercise the most tender care in rearing and feeding them. When hatched, the young are quite naked; but the soft, downy, and warm lining of the nest affords them the requisite comfort in this state. Such is the friendly attachment of the old birds that they associate with their offspring till the following spring. During the autumnal and winter months the entire family may be seen flitting from tree to tree in social union, and never once commingling with other associates. They are distinguished by their incessant shrill cry of "troole, troole," which may be heard at a great distance. They repeat this cry almost without intermission when either perched on the tree top, or flying in the air. Their flight is performed by jerks and vibrations, always in an up and down direction; and when they perch upon a tree they always select the extremity of the highest branch for the purpose of enabling them to dart with more certainty and effect upon their prey. The method to which they resort in the killing of their larger prey is well illustrated in the following anecdote recorded by Edwards. "Mr Bell, while on his travels through Russia, had one of these birds given him, which he kept in a room, having fixed up a sharpened stick for him in the wall; and on turning small birds loose in the room, the butcher bird instantly caught them by the throat in such a manner as soon to suffocate them, and then stuck them on the stick, pulling them on with bill and claws; and so served as many as were turned loose, one after another, on the same stick."

The American bird which has been frequently referred to this species, and which is similar to it in most respects, but differs from it in others, appears to have exactly the same habits; and those habits are so well described by Wilson, that we cannot resist quoting a short passage.—"I have seen him," says the great ornithologist of North America, "in an open field, dart after one of our small sparrows with the rapidity of an arrow, and kill it almost instantly. Mr. William Bartram long ago informed me, that one of these shrikes had the temerity to pursue a snow bird (*F. Hudsonica*) into an open cage, which stood

in the garden, and, before they could arrive to its assistance, had already strangled and scalped it, though he lost his liberty by the exploit. In short, I am of opinion, that his resolution and activity are amply sufficient to enable him to procure these small birds whenever he wants them, which, I believe, is never but when he is hard pressed by necessity, and a deficiency of his favourite insects; and that the crow or the blue jay may, with the same probability, be supposed to be laying baits for mice and flying squirrels, when they are hoarding their Indian corn, as he for birds, while thus disposing of the exuberance of his favourite food. Both the former and the latter retain the same habits in a state of confinement; the one filling every seam and chink of his cage with grain, crumbs of bread, &c., and the other sticking up, not only insects, but flesh, and the bodies of such birds as are thrown to him, on nails or sharpened sticks fixed up for the purpose. Nor, say others, is this practice of the shrike difficult to be accounted for. Nature has given to this bird a strong, sharp, and powerful beak, a broad head, and great strength in the muscles of the neck; but his legs, feet, and claws are by no means proportionally strong; and are unequal to the task of grasping and tearing his prey, like those of the owl and falcon kind. He, therefore, wisely avails himself of the powers of the former both in strangling his prey, and in tearing it to pieces while feeding.

"The character of the butcher bird is entitled to no common degree of respect. His activity is visible in all his motions; his courage and intrepidity are beyond every other bird of his size, (one of his own tribe only excepted, *L. tyrannus*, or king-bird;) and in affection for his young he is surpassed by no other.

"He associates with them in the latter part of summer, the whole family hunting in company. He attacks the largest hawk or eagle in their defence, with a resolution truly astonishing; so that all of them respect him, and on every occasion decline the contest. As the snows of winter approach, he descends from the mountainous forests, and from the regions of the north, to the more cultivated parts of the country, hovering about our hedge-rows, orchards, and meadows, and disappears again early in April."

The species of shrikes enumerated by different writers are very many; but many of them are not easily distinguishable from the fly-catchers, to which the shrikes generally are closely allied; and we must content ourselves with a selection.

RED-BACKED SHRIKE (*L. collaris*.) This species, which is rather a handsome one, appears in some districts of Britain as a summer migrant. It comes in May and departs in September, so that it is in the country only during the time that the larger summer beetles are in a state of maturity and on the wing; accordingly those beetles constitute the principal part of its food. This and some others of the insectivorous birds which regularly visit Britain, confine themselves to particular districts. The nightingale, for instance, appears only in the south eastern parts of the island, and in these it is less common and less melodious in its song, upon the cold retentive clays than upon the warm gravels. The shrikes, and fly-catchers, which are nearly allied to the shrikes in their habits, are more partial to the central parts of the country, ranging along where the prevailing strata are oolites and stiff clays; and they seem to prefer the winds from the Atlantic to those from the

eastern sea ; for the species under consideration is more numerous, and also extends further north on the west side of the island than on the east side.

As is the case with very many birds, especially with those which are only visitants and are local, the habits of the red-backed shrike have not been observed with the requisite degree of care. It has been unfortunate for the natural history of the British islands, that those who have had opportunities of observing animals in free nature have seldom been writers, while those who have been employed to write have as seldom been observers. In consequence of this very many of the printed descriptions of British birds have been compilations from foreign describers, where the physical characters of the country are very different from what they are with us, and the consequence is, that they do not answer correctly to what is observed in this country, and thus our written history and our living nature are very often at variance with each other ; and it will take more time and labour to correct the blunders which have thus been committed, than it would do if the subject were unstudied, and free from this contamination.

The red-backed shrike is a very lively bird ; and it so far resembles the birds of prey that the female is considerably larger than the male. The female is seven inches in length and twelve in the stretch of the wings, and weighs an ounce and a quarter ; while the dimensions of the male are six and ten inches, and the weight only one ounce. The prevailing colours of both birds are reddish brown on the upper part, and soft greyish white on the under ; but the under part of the male has a tinge of rose colour, while that of the female, still preserving the slight resemblance to birds of prey, is marked by dusky lines, as is the case with the larger grey species. This one stands accused of sometimes killing little birds ; but if it does so, those birds do not show the same hostility to it which they generally show to enemies, whether of themselves or of their nests. The little birds may frequently be seen collecting their numbers in order to annoy the smaller hawks as killers of birds, or the cuckoo as a violator of nests ; but they do not thus annoy the red-backed shrike, or indeed any of the shrikes. We may hence conclude that these birds are not habitual enemies of the smaller ones, otherwise the habitual instinct which displays itself against such as are known to be enemies would be displayed against them. Still these birds are exceedingly active ; and when they are watching for their prey they are in a state of constant excitement. As is the habit of all the *graus*, they frequent hedges, coppices, and the margins of woods ; and while they sit perched on a twig, they keep their body worked into that excitement which can enable them instantly to dart upon that against which they proceed. In this state the tail is expanded, the wings partially spread, the bill open, and the eye expressive of the utmost irritability. It has been reported of them that when thus excited, and no prey comes in their way, they can charm the fledglings of the small hedge birds within their reach, by imitating the calls of the parents ; but the truth is, this matter has not been clearly established ; and in many respects the ash-coloured shrike has been mixed up with the history of this one.

The nest of the red-backed shrike is very carefully hidden, and it is also neatly made. It is usually placed in a close hedge or bush, or in one of those

short but thickly branched trees which are so common on the margins of forests. Externally, it is composed of mosses and vegetable fibres, mixed with wool ; and the inner part is composed of hair, very neatly interlaced together. The eggs are five or six in number, having the ground colour whitish, but with the same blush of rosy tinge which characterises the under part of the male bird ; and they are marked with spots of reddish brown. The young, as is the case with most birds which are for the greater part of their time upon the wing, remain long in the nest, and are diligently fed and carefully attended to by their parents. When they quit the nest, they bear a good deal of resemblance to the female, only they are not so red on the upper part.

The red-backed shrike, though very energetic, and much upon the wing in short flights, is far from being a graceful flyer. It gets through the air by a succession of leaps, in each of which it mounts considerably upward, and drops down again at the end ; and it never rises into high flight while it is on its feeding grounds. The chief cause of this kind of flight appears to be the shortness and breadth of the wings, which prevent the bird from floating easily, so as to renew its impetus without descending below the line of its motion. When it migrates, as it unquestionably does, it in all probability takes a higher flight ; because we could hardly imagine a bird to cross even the narrowest part of the Channel, with such a low and leaping flight as the shrike exhibits in those places where it takes its abode.

WOOD-CHAT SHRIKE (*L. rutilus*). This is a more powerfully-winged, and altogether a more energetic and discursive bird, than the last-mentioned species. In Britain it is rare ; and though its nest has been found in Norfolk (which by the way is a remarkable county for birds), it can hardly be regarded as any other than a straggler, inasmuch as neither the nest nor the bird have been observed regularly every year. On many parts of the continent of Europe it is by no means rare in the summer season, but it disappears rather early in the autumn ; and is understood, like many of the summer migrants of Europe, to take up its abode in Egypt during the winter. As this species does not resort regularly to the British islands, it does not take a definite locality, but is generally found in those situations to which a side wind is most likely to blow it from the continent.

It measures about the same length as the female of the red-backed shrike, namely, about seven inches ; but its wings are eighteen inches in stretch, which is three inches to each wing more than in that bird ; of course it is much more capable of extended flight, and the style of its flying is altogether far more graceful. Its bill is dusky with a bluish tinge, stoutly made, very firm in the texture, and very decidedly notched towards the tip ; the legs are dusky, and the claws black, very firm, pointed, and much hooked, so as to resemble in form the talons of a bird of prey, but they are much shorter in proportion to the size of the bird, and are to be regarded as perching or climbing claws rather than as killing ones. The forehead, or band down each side of the neck to the shoulders, the lesser coverts of the wings, and part of the quills, are dusky, or even in some instances black ; the roots of the primary quills and the points of the secondary ones, and also the feathers on the scapulars, are white. The hind part of this head is rust-coloured, and the back dark ash ; the throat, front

of the neck, and breast, are dull white, passing into yellowish on the belly and toward the vent feathers. The tail is long and strong, and a little rounded at the extremity; it is of a dusky colour, not quite so dark as that on the head, neck, and quills; and the rump feathers and upper tail coverts are still paler, dusky, and mottled with white. Altogether it is a very handsome bird, and perhaps it is to be regretted that it does not visit the country in greater numbers, or more regularly; for, on account of its activity and great power of wing, it cannot fail to be a great destroyer of insects, and as such very serviceable to vegetation.

CAROLINA SHRIKE (*L. Carolinensis*). This bird bears a considerable resemblance to the larger shrike of America, but it differs so much in size, in colour, in locality, and in habits, that it must be considered as a distinct species. Both are migratory birds, and appear in the United States only during the summer, retiring to more southerly climates as the severe weather sets in. The greater shrike, however, takes up its summer abode in the northern and middle states rather than in the southern; while the species now under consideration, though abundant in the southern states, very rarely appears in the northern. The rice plantations, on the damp and fertile grounds in Carolina and Georgia, are its principal haunts, and it is protected by the growers of rice as a bird which renders them essential service. The service which it renders is the destruction of mice, which are particularly injurious in those places. It takes its post on the fence enclosing the stacks of rice, watching with the same keen and persevering eye as a cat, and the instant that a mouse makes its appearance the bird darts upon it with the rapidity of lightning, and despatches it. Its feeding is not exclusively confined to mice, for it feeds on crickets and grasshoppers, and many of the larger insects, which both as larvæ and in the full grown state, are highly injurious to the crops. On this account it is an exceedingly valuable bird; and indeed there are very few birds so valuable to the cultivators of vegetables as those which clear the crops of destructive insects, and therefore it behoves all cultivators to understand well the nature and the food of those birds which come about their grounds; for there are many indiscriminate destroyers of every winged creature that they can kill, who exterminate, in as far as they are able, those very birds which are the best protectors of their favourite plants, inasmuch as they consume those destructive creatures which human labour cannot reach.

The Carolina shrike builds its nest near the ground, generally in close but detached bushes; and the sound which it utters in the pairing season is disagreeable and creaking. It evinces the same attachment for its young which is shown by most species of the shrike.

It is a short-winged bird in proportion to its size, and therefore does not take long flights, though it is certain and rapid in short ones. It measures about nine inches in length, and thirteen in the stretch of the wings. The colour on the upper part is dark ash; the scapulars and line above the eye is whitish; the wings black, with a small spot of white at the base of the primaries, which are pointed with white; a black streak extends along the front through each eye, reaching half way down the neck; the eye is dark hazel, shallow under the eye-brow; the four middle feathers of the tail are entirely black; and the four exterior ones on both sides are tipped with

white more and more to the marginal one, which is almost all white, which colour prevails in the whole lower parts. In some specimens, the males and females both exhibit transverse lines of a pale brown colour. The female is rather smaller in size than the male, and considerably darker in colour, both on the lower and the upper parts; but the black does not extend so high on the first as it does on the male.

In America, which is a great country for insects, the species of insectivorous birds with notched bills adapted for the destruction of the larger insects are exceedingly numerous; but in many instances it is impossible to draw the line between them, so as to separate what are fly-catchers from what are shrikes, though it is probable that the greater number are entitled to rank with the first of these divisions. The king bird, or tyrant fly-catcher, has all the boldness of the shrikes; but still it evinces no disposition to kill little birds, though it attacks in defence of its young the very largest species with the utmost determination, and is quite sufficient to drive off even the most powerful of the birds of prey.

THE GREAT SHRIKE (*L. curvius*), is a native of Africa, having the upper parts mottled with brown russet and ash colour, with the middle of the feathers black; a large fawn-coloured spot over the eye, and a dull brown on the ear covert; the quills have their upper webs russet, and are bordered with yellow, but ash and grey on their under sides; they are greyish white with a rose-coloured tinge, on the flanks; the bill is of a yellow colour, and the feet are dusky black. The colours on the female are less brilliant than those on the male, and the under part is streaked with dusky lines. The length of this species is about thirteen inches.

OLIVE SHRIKE (*L. olivaceus*), is another African species, much smaller than the preceding, being only six inches in length, and differing greatly from it in the markings of the colours. The upper parts are olive green; the quills blackish, bordered with olive green; the tail feathers yellowish, except the two middle ones, which are green; the bill and feet are brown, and the forehead and under parts yellow.

Some shrikes have the head crested, among which may be mentioned the crested shrike of China, and that of New Holland. The first is about seven inches and a half in length; it has the upper part brown, and the head black on the upper part, but with a brown crest; the cheeks, the throat, and the forepart of the neck are white, with a black streak extending from the gape, and a small red spot on the eye; the tail feathers are staged in the same manner as those of the magpie; they are brown for the greater part of their length, but white at the tips; the bill and feet blackish. The New Holland crested species is pale green, on the upper part is of the same colour; but the upper part of the neck, the quills, and the tail feathers are blackish; the under parts yellowish brown; the back yellow, and the feet brown.

In southern Africa, in Madagascar, and the adjoining islands, and in all the islands to the south and east of Asia, and also in the richer parts of south-eastern Asia, which have a comparatively moist climate, and consequently a nearly constant vegetation, with a corresponding abundance of large insects, shrikes, as well as fly-catchers and other birds that feed chiefly upon insects, are exceedingly numerous, and they vary much both in size and in colour. Their

habits are, however, so nearly allied to those of the species that have been already noticed, that a repetition of them would be unnecessary, and a mere enumeration of sizes and colours could not convey much useful information to the general reader; for which reasons we shall not enter into the details of them.

Shrikes are altogether rather an interesting genus of birds, on account of the kind of food which they consume, which consists chiefly of small animals that are particularly annoying to cultivators. In the system they hold a sort of intermediate place between the birds of prey, properly so called, and the crow tribe. They have the feet of the latter, but their bills approximate those of the former; and though many of them kill and eat smaller birds, there are none of them which rob the nests of the eggs that they contain, as is done by many of the crows; and they are not nearly so miscellaneous in their feeding, or so capable of subsisting upon vegetable substances, as crows are; and, therefore, when their insect food fails, they are under the necessity of shifting their quarters by migration. The style of their flight is also different from that of the crows, and so are the marking of their colours.

LANTERN-FLY. The name of a supposed luminous insect (see *FULGORA*), to the account of which we have to add, that the prince of Nieuwied, whose extensive researches in the Natural History of America which have so much contributed to elucidate many disputed points, render his recent decease an irretrievable loss to zoology, never observed the least traces of luminosity in the Brazilian lantern-fly during his travels in South America; whence the question of the supposed luminous powers of these insects which has lately been discussed at such an inconvenient length in the Entomological Magazine, may be considered as decided in the negative. Donovan, indeed, represented the Chinese species as emitting a white light from its snout whilst hovering in a bunch of chrysanthemums; but the artistical talents of this writer were too evident in all his works to allow any weight to be given to his authority in such a disputed point as the present. Another figure, with still less correctness, has made the rays spring, not from the snout, but from the body.

LAPIS LAZULI. The azure stone, or sapphire of the early mineralogists. This beautiful mineral is found in Persia, Bucharia, China, and in the neighbourhood of the Ural chain of mountains. It forms a considerable article of commerce in China, as it is used in ornamenting the best sort of earthenware manufactured in that country. It is found massive, disseminated, and in rolled pieces, the fragments being indeterminately irregular.

Lapis lazuli is much prized by lapidaries, on account of the fine polish it is capable of receiving; and as such, it forms a beautiful ornament in the formation of boxes and other small works of art. The usual belief, that it owes its beautiful colour to copper, is erroneous, as the most careful analysis furnishes no trace of that metal; iron is, however, found in considerable quantities. The name *ultramarine*, given to the pigment obtained from this mineral, is said to have been bestowed on it in consequence of the stone having been brought from beyond the sea. Lapis lazuli was once used in medicine, and from the splendid yellow veins that it presents, was called the "golden remedy."

LAPWING (*Vanellus*). A genus of *echassiers*

or stilt birds, belonging to the pressirostral division, and nearly allied, in many of their characters, to the plovers and oyster-catchers, but sufficiently distinguished from both to entitle them to be ranked as a distinct genus; and, indeed, although the species are not very numerous, they admit of division into two sub-genera, lapwings, properly so called, and plover lapwings. The name lapwing alludes to the sound which these birds can make, either by striking the turns of the wings against each other over the back, or by striking the points of them with great force against the air; and the systematic name, *Vanellus*, is given to them on the same account. It means relating to a fan, or, as one would say, fan-bird, because the sound produced by the stroke of the wings is very similar to that made by suddenly opening a fan, or striking it forcibly against the air, in two parts of this exercise of the fan which is so humourously described in the Spectator.

The characters of the genus, taken as a whole, are as follows: the bill short, slender, straight, compressed, and enlarged at the tips of both mandibles; the basal part of the upper mandible furrowed by nasal grooves, in which the nostrils are placed laterally, and pierced longitudinally in a membrane which covers the groove. The feet are slender, and furnished with four toes, of which three are turned to the front, and the middle one united to the outer by a short membrane. The hind toe is always very short, and sometimes merely rudimental, or entirely wanting; and it is articulated so high upon the tarsus, that the point of it does not touch the ground in walking. The wings are, generally speaking, pointed; the first quill is the shortest, and the fourth and fifth are the longest in the wing. In some of the foreign species, the bastard wing is armed with a spur; and the presence or the absence of this is sometimes made the ground of subdivision, though so far as we are aware there is no other character which depends upon or follows this particular one.

Lapwings, as we shall see presently, are highly interesting birds, and therefore it is necessary that we should attend with some care to the characters of the three principal parts of their external organisation, the bill, the feet, and the wings. The slenderness and shortness of the bill both tend to give the bird very great command over it; and the enlargement of the mandibles at the tip enables it to snap and seize with great celerity. This suits well with the chief food of the lapwing, which consists of earth worms and insects, the former of which especially are exceedingly sensitive to everything that agitates the surface of the ground, and must be seized in an instant, otherwise they escape into their subterranean retreats. The feet are equally well fitted for light walking at a rapid pace, as the whole of the weight is always borne upon the three toes only, and thus the elasticity of all their joints comes into play; and the movements of the lapwing upon the ground are inferior in ease and rapidity only to those of the few genera of stilt birds, which are entirely destitute of the hind toe, and which are in general much less clever on the wing than the present genus. The wings are, however, perhaps the most beautiful part of the whole structure, admirably as the birds are formed in every respect. They are, as we have noticed, pointed wings, but the point is in the middle of the breadth, so as to divide the horizontal spread of the wing into nearly equal parts; and what is wanting in this respect is supplied

by the very peculiar bend of the wings of those birds. This gives them a very decided advantage over those birds which have wings pointed in their first quills, and straight in their general lines, such as are the wings of the swallows and swifts. These can turn laterally upon the points of the wings as pivots, with perhaps more celerity than the lapwings; but the lapwings can turn upwards or downwards, or in any oblique direction, much more cleverly; so that if we take all the possible directions of a wing into the account, there is perhaps no bird which has such perfect command of the air as the lapwing; and there is none which displays such antics in its aerial movements, or the contemplation of which is a more beautiful study, in the finest branch of animal mechanics. At the same time the birds are very elegant in their forms, compact and neat in their plumage, lively in their manners, inoffensive and uninjurious to man in their feeding, and altogether among the most interesting of the feathered race, though they are birds of the wilds, rather than of fertile and highly cultivated places, and discursive and migrant at different seasons of the year.

We shall now notice the principal species, and in doing this we shall begin with the typical one, or the lapwing properly so called, which is well known in all the swampy wilds of rather upland places in the British islands, and which is as much admired as it is well known, from the beauty of its form, and the singular energy and activity of its manners.

THE CRESTED LAPWING (*V. cristatus*). This is a bird which is pretty generally distributed, and which forces itself upon the notice of all the observers, on account of the brightness of its colours. The top of the head, the nape, the upper part of the neck, and the breast, are black with metallic reflections; and the feathers on the hind part of the head are formed into a beautiful fibrous crest. The upper part is a sort of mottled green with very rich metallic reflections. The quills of the wings are pure white, except a considerable space at the point, which is black, with the exception of the two external ones, and these are white for the whole of their length. The sides of the neck and all the under parts are pure white. The under tail coverts are russet; the bill is black; and the feet brownish red. The length of the full-grown bird is between eleven and twelve inches. The young before the first moult have the crest very short, a black patch under the eyes, the throat clouded with white and ash colour, and the greater part of the feathers on the upper part margined with russet-brown. The plumage both of the old and the young is subject to some variations, though the causes of these variations have not been investigated.

Lapwings are common in every part of Britain which is adapted to their habits; but unless it is on the sea-shore, and indeed even there, they are birds of seasonal appearance. In the breeding season they disperse themselves over the interior of the country, and seek those marshy places of the moors which are removed from human habitations. They are not found exclusively on the uplands; for their habit is not particular as to elevation above the level of the sea, their proper situation in wild nature being that ground which is intermediate between the wet and the dry, but rather nearer the former; and in such situations they are found from the margin of the salt marsh, which is barely elevated above the level of

the sea, to the margin of the uppermost bound which is found on the slope of the mountain.

As is the case with many other birds of the same order, and especially of the same family, the lapwings are to be considered as dispersive rather than as migratory in the summer. When the winter sets in, and those small animals upon which they feed are either buried in the earth or confined, or treasured up in the egg, in the inland parts of the country, they resort to the sea, which, in all latitudes where it does not freeze, knows no winter as a sterile season in which it cannot supply food; and when the summer approaches, they disperse themselves over the country, each species resorting to that situation in which it can find the most abundant supply of food for itself and its young, and where its labours in the procuring of that food are of the greatest benefit.

The common lapwing, as is the case with most birds of the family, makes no regular nest, but merely smoothes and partially clears of herbage a little space under cover of the grass or heather. The eggs are four in number, as is the case in almost the whole of the family, and they are arranged in a regular quatrefoil or cross of four leaves, the small ends being almost in contact at the centre, and their large ends disposed outwards so regularly that the axis of each opposite pair form a straight line, and those of the two pairs are at right angles to each other. The ground colour of the eggs is of a pale greenish olive, and they are marked over with blotches of dusky and rather brownish black, which are more numerous and larger toward the large ends of the eggs than the small ones. The young are capable of using their feet cleverly almost the moment they leave the shell; but they are for some time covered with down, and not with feathers; and some time elapses before they are capable of flight. It is not long, however, before they are enabled, partially at least, to find their own food with comparatively little assistance from the parent birds; and until they are fledged and can use the wing, they are but rarely seen, as they crouch and conceal themselves among the herbage. By this means they are safe from ravens and other enemies, which prowl about the same sort of places in which lapwings are bred; and there is no doubt that the simplicity of the place where they are deposited, and the inconspicuous colour of the eggs, also contribute a good deal to the safety of the nest.

But in addition to those natural means of concealment, which do not call into exercise the instinct of the birds, lapwings are more assiduous, and perhaps more dexterous in decoying suspicious visitors away from their nests, than any birds with which we are acquainted. They do not show the least alarm, or resort to any stratagem in the case of sheep or cattle, but remain as quiet when these are ranging the places where they nestle, as if there were no animal there but themselves. Their next neighbour toward the hill, the plover, and also the snipe, which comes between them and the marsh, give them just as little alarm; and they are in no ways disturbed by hares, grouse, or any of the inhabitants of the wilds which do no injury to the nests of birds. If, however, a carrion crow, or a hooded crow, which is a more frequent visitor of their haunts, especially in the northern parts of the British islands, makes its appearance, they are up in arms; and as there are generally, if not invariably, more than one pair upon the same breeding ground, the whole are in the air and in

arms, if it is before the sitting is commenced or after the young are hatched, or all the males are so if it is during the time of incubation. Their gestures in the air upon such occasions are highly amusing; and if the enemy is on the wing they speedily batter him from the locality by striking at him, not with the bill, but with the turn of the wing, and they strike so rapidly and so hard, without in the least disturbing their own poise, that even the raven himself, strong as are his wings, and formidable as is his bill, is glad to make his escape from them. If the enemy is on the ground, a dog for instance, they annoy him even more; but while some one feigns lameness, and tempts him on to the pursuit, the others keep flying and wailing about him, and making the sound of their wings ring in his ears, till he is both bewildered and exhausted; and when a cur happens to cross the breeding ground of lapwings, he experiences as fatiguing and as profitless a hunt, as mongrels do with a hare, of which the first sight is the nearest. Lapwings are not quite so violent against human invaders of their breeding grounds, as they are against the predatory birds and quadrupeds; but still they exhibit enough of excitement to show that human beings are not very welcome visitors. They wheel about in the air, uttering their plaintive cry of *pee-wee*, in a state of no small excitement, while as they turn, which is often within a few inches of the intruder, the smart twitch which they give to the air with their wings sounds in the ear as if a blow were actually given. The cry is very wailing and melancholy in the sound, and the birds seem in great distress; but it is possible to subdue their excitement, and observe them on the ground conducting themselves with much apparent complacency, as if they felt grateful for not being injured. If one chooses to walk for a little while backwards and forwards over the breeding ground of lapwings, it is not long before the whole of them suspend their clamour and their aerial activity, descend to the ground, and in perfect silence run about, as if showing themselves to him and claiming his acquaintance, and if it is a fine day, so that the sun brings out the metallic glances of the colours, it is impossible to imagine a finer sight than those running lapwings, which are perfectly familiarised to the observer, and will run almost to his feet without the least apprehension. If the herbage is not beaten, as if one were searching for nests or young ones, their excitement soon goes off, and they allow themselves to be approached within a very short distance. Indeed, they have little or no apprehension or dread, except for their eggs or their young, because they are so clever both on the foot and the wing, and can get so readily from the one to the other, that they have less occasion to fear enemies than almost any other birds. To the kite and the sparrow-hawk they are perfectly indifferent, because the first of these has scarcely courage sufficient for attacking so large a bird as a lapwing; and the second is so moderate in the velocity of its rush, though otherwise a formidable creature in proportion to its size, that the lapwing can get out of its way. Even the gos-hawk makes but little prey of the lapwing; but if the ger-falcon comes in the way, the doom of the lapwing is sealed notwithstanding the number and variety of its manoeuvres. Yet, even the ger-falcon cannot get the better of the lapwing without gaining its topmost sky, and putting in exercise its most powerful rush; and therefore the cap-

ture of a lapwing by a ger-falcon is one of the finest sights in the whole action of birds.

Earth-worms are understood to constitute at every season of the year the principal food of the lapwing; and as those worms are always under ground when the sun is out, the birds are obliged to feed early in the morning, and thus they have the bright part of the day for repose, for sport, or for those manoeuvres which they exercise in order to entice enemies, or suspected enemies, away from their nests and their young. We forgot to mention, when speaking of their resources in this way, the artifices of the female when sitting. As she and her nest are generally concealed under cover of vegetation of some kind or other, she does not rise readily; and as the male has fed before the time that visitors are generally abroad, he is in the vicinity, and on the alert to play off all his wiles for the purpose of keeping the female and the nest undisturbed and in safety. If, however, he should not succeed, and danger approaches nearer than the distance at which the instinct of the female teaches her that she is safe, she makes her escape from the nest. But she always plans it such a manner as that she can run unobserved before she rises; and if the danger is not very near, she runs to meet it, and then springs upward as if just started, and makes off in a direction which takes her still farther from it. In her progress she counterfeits lameness or mutilation, and tumbles along as if her legs or wings were broken, in order as it were to tempt the enemy with an easy capture; and if that enemy is a dog, especially a cur which runs indiscriminately at every thing, she is generally successful in her enticement. The pursuer very often gets nearly up to her, and this nearing induces him to proceed; but whenever he comes almost to close quarters, the apparently crippled bird gets very easily on the wing, and dashes so far in advance that she can again descend to the ground and practise her feigned lameness. When by the continuance of these stratagems she has succeeded in enticing the enemy to a sufficient distance from the nest, she rises on the wing, dashes off at rapid flight in another direction, doubles after a certain distance, and returning alights on the opposite side of the nest, and then runs to it in the same hiding manner with which she quitted it at the first. In consequence of these manoeuvres, the nest of the lapwing is very rarely seen in proportion to the numbers of the birds; and when seen, it is rather by accident than from being betrayed by the rising of the female.

In the upland districts where lapwings, generally speaking, breed, we believe (though the fact has not been absolutely ascertained) that earth-worms, which constitute the principal food of these birds, pair only once a year, and that at the season when the lapwings have their broods, and stand most in need of provisions. But in the lower and warmer regions, the same worms are understood to pair twice in the year, namely, in the spring and in the autumn; and as they are in the best condition and most above the ground during the pairing time, they furnish the birds with an ample supply of food, both at the time when they are dispersed over their breeding places, and at those when they are on their journeys from and to the perennial pastures of the shores of the sea.

In many of the books which profess to treat of natural history, and which, like most professions and

professors, give the romance instead of the reality—the enticing nonsense rather than the instructive truth—it is asserted that the lapwings can, by the tread of their feet, force the worms out of the ground, and thus by their own exertions collect to the surface a supply of food for themselves. This, however, very much resembles the pretended capability of Owen Glendower of calling spirits from the vasty deep, as it is not likely that the worms would answer to any call which might be made upon them to come out of the ground in order to be eaten. The fact, indeed, is quite the reverse; for any agitation of the surface of the ground invariably sends the worms farther down, instead of bringing them to the surface; and this is proved by the conduct of earth-worms when hunted by the mole, for they always endeavour to get below the runs of that animal, instead of resorting to the surface, in order to escape from it. Besides this, the lapwing is so light an animal, that any concussion which it could give to the earth with its feet could not affect earth-worms, delicate as they are; and the peculiar elasticity of its feet, and the lightness of its tread, are obviously intended to prevent it from alarming its vermicular prey, and driving them into the earth by any concussion which it may impart to the surface. Such are a few particulars of the history of the common or crested lapwing, which is, all circumstances considered, one of the most interesting of British birds; and one which, notwithstanding its wailing notes and the waywardness of its manner, is one of the most interesting in every place where it makes its appearance.

THE GREY LAPWING, OR GREY PLOVER (*Squatarola cinerea*) is a bird nearly allied to the lapwing, but holding a situation intermediate between it and the plovers. It is not so large or so weighty a bird as the lapwing, neither is it so powerfully winged in proportion to its dimensions and volume. The lapwing measures nearly fourteen inches from the point of the bill to the extremity of the tail, and two feet and a half in the expanse of its ample wings, and its weight is at least half a pound when it is in good condition. The species now under consideration is only twelve inches in length, and two feet in the expansion of the wings; and it is an ounce, or an ounce and a half, lighter than the lapwing. It is, however, a more elongated bird, in proportion to its length, than any of the other two; and for this reason it is probably a bird of more powerful wing. Its bill is also longer in proportion than that of either the lapwing or the plover; and the hind toe is merely rudimentary, being destitute of a claw, and never of such length as to reach the ground. The wings are also of a different construction from those of the common lapwing. They are pointed wings, but the point is not in the same part of the wing; for while it is in the middle in the common lapwing, it is in the anterior part in this bird, the first quill in the wing being the longest. Its habits are but little known, though it is probable that it occurs in more parts of Britain than is generally supposed. Small flocks, consisting of old ones and young ones blended together, appear on different parts of the season, and there is reason to believe that the young members of those flocks are reared within the country; but too little is known of the habits of the bird in its breeding places, to enable us to draw any certain conclusion respecting it. It is an upland bird in respect to its breeding ground; but as a British bird, it appears to resort only to those

places which are nearest to the continent of Europe; and we believe that, during the summer season, it is more frequently met with in the mountains or hills in the county of Kincardine, than in any other part of the British islands. In England, it appears only in the winter season, and chiefly on the coasts, which shows that it is a bird which spends the summer in more inclement regions; but it is so local and comparatively rare, that no distinct conclusion can be come to respecting it.

THE SPURRED LAPWING (*V. albicollis*) is the only other species which we shall notice. It is of a rich grey on the upper part; the breast and the belly, the cheeks, the sides of the head, and the throat, are streaked with black and white, and there is a yellowish appendage to the head arising from the front and neck. The quills are black, the middle coverts of the wings bordered with white, the tail feathers whitish, the bill yellow, the feet orange, the length is thirteen inches, and the turn of the wing is armed with a spur.

LARCH is the *Larix Europæa* of Decandolle. It belongs to *Conifera*, and though a native of Germany, it is one of our most plentiful forest-trees. The larch is remarkable for the conical elegance of its growth, and the durability of its timber; in the last respect even rivalling the oak. The trees are readily raised from seed; and after being planted in rows in the nursery for a few years, are fit to be transplanted into their final stations.

It is considered an Alpine tree, being remarkably hardy; and, therefore, vast numbers of them have been planted on the mountains and poor wastes of Great Britain and Ireland within these last four-score years. The late dukes of Athol have been most successful planters; large tracts of hilly country, on the Athol estates, have been clothed with the larch, to the incalculably increased value of that in other respects almost barren possession. Nor has the introduction of this tree been confined to the Highlands; as they have been planted everywhere to the great advantage of the planters.

"In 1809, larch timber, grown by the duke of Athol, at Dunkeld, was first used in the British navy at Woolwich, in the building of the *Serapis* store-ship, the *Sybil* frigate, the bottom of a lighter, and for piles driven into the mud, alternately wet and dry; and in all these stations proved a durable wood. The *Athol* of twenty-eight guns was also built entirely of larch timber from his grace's estate; and at the same time the *Niemen* of the best Riga. After their first course of service, on being examined, the *Niemen* was found in a decayed state, and condemned accordingly; whilst the *Athol* was again put into commission, and is at this time (December, 1832) on a voyage to the West Indies. It was also remarked that, during the time this larch timber lay in Woolwich dock-yard, exposed to the weather, neither the heart or sapwood was in the least decomposed; nor was there the slightest appearance of fungi growing upon it."

Mr. Pontey, forester to the duke of Portland, in his "Forest Pruner," highly recommends the larch as a durable timber tree, and hundreds of thousands have been planted at his instigation.

Within these five or six years, however, it has been found that the larch, in various parts of this country, has become liable to a serious defect called *pumping*—that is, from the decay of the heart-wood, the tree becomes hollow like a pump. Much has been written on the subject, but no satisfactory reason has yet been

given as to the immediate cause of it. It has occurred to single trees in the midst of hundreds of sound ones, on poor thin gravels and on rich loams, and on both wet and dry soils; whilst in other situations, where all these varieties of soil and circumstances exist, nothing of the kind has been observed. Many eminent arboriculturists are now studying the matter, and it is to be hoped that some clue will be discovered, which will lead to the cause of the failure.

The larices differ from the cedars by being deciduous. There are four species—the common, the daurian, the red or small fruited, and the black or pendulous. The last is chiefly remarkable for the graceful curve its leading shoot assumes, drooping towards the ground when about fifteen or twenty feet in height, and forming a natural arch of extreme elegance and beauty. The red is a slow-growing tree; and its timber is so close and heavy that it will hardly swim.

LARKSPUR is the genus *Delphinium* of Tournefort, an extensive family of beautiful flowering annuals and perennials, chiefly natives of Europe. The *D. grandiflorum*, and its varieties, are among the most splendid ornaments of the flower garden; and the great variety of colours in the annual species makes them universally admired.

LARVA. The technical term given to that state of the life of an insect immediately succeeding its escape from the egg, and previous to its assumption of the pupa state. See **INSECT** and **CATERPILLAR**.

LASIOCAMPA (Schränk). A genus of large lepidopterous insects, belonging to the section *Nocturna*, Latreille, family *Bombycidae*, and containing the egg-moths, a name given to these insects on account of the compact egg-like cocoon which they spin. The spiral tongue of the perfect insect is obsolete, the palpi minute, the antennæ strongly bipectinated, wings strong and rounded, the legs scarcely hairy. The larvæ are hairy, woolly bears as they are termed in some parts of the country, and roll themselves up in a coil when disturbed. The type is the *Bombyx rubi*, or fox-egg; and there are four or five other British species. Latreille introduces several other genera into the group, such as *Odonestis potatoria*, *Gastropacha quercifolia*, &c.

LASIOSPERMUM (La Gasca). A genus of ornamental trailing plants, natives of the south of Europe. They belong to *Compositæ*. The hardy species appear in the flower border, and were formerly called *Santolina*.

LATHRÆA (Linnæus). The *L. squamaria* is a very curious British parasitical plant. The roots attach themselves to those of trees or shrubs, and thence extract nourishment. The flowers are didynamous, and the plant belongs to the natural order *Orobanchææ*. This plant is rather rare, and found only in dry woods among leaf-mould. Its English name is toothwort, from the shape and colour of its bracteous scales.

LATHROBIUM (Gravenhorst). A genus ofrove beetles (*Brachelytra*; sub-family *Staphylinides*), having the body long, slender, and nearly cylindric, with the last joint of the maxillary palpi minute and pointed; the antennæ are inserted near the base of the mandibles, and the anterior tarsi are dilated in both sexes; last joint long. Fifteen British species. Type *Stroph. elongatus*, Linnæus.

LATHYRUS (Linnæus). A genus of elegant climbing plants, chiefly natives of Europe. Class and

order *Diatelphus Decandria*, and natural order *Leguminosæ*. Many are ornamental, and some very useful as agricultural plants. In this genus, we find the everlasting pea (*L. sylvestris*), the sweet pea (*L. odoratus*), the Tangier pea (*L. Tangitanus*), the broad-leaved everlasting pea (*L. latifolius*), the chichling vetch (*L. sativus*), and the hairy vetch (*L. hirtus*); the two latter agricultural.

LATIRA. A genus of molluscs constituted by De Montfort, but properly belonging to the genus *Fusus*, with which it is now classed.

LATRIDIUS (Herbst). A genus of minute coleopterous insects of doubtful situation, placed by Latreille amongst the *Xylophaga*, and by Stephens in the family *Engidæ*, having the abdomen oval and broader than the head and thorax, the basal joint of the antennæ very large and globular, terminal joint large, palpi very minute. The type is the *Tenebrio lardarius* of DeGeer, by whom the transformations of this little beetle were observed, and of which he found the larvæ feeding upon cured pork. Marsham called this group *Corticaria*; but some of the smaller species having been considered as generically distinct, Herbst's prior name was retained for the typical species, and Marsham's given to the others. There are about twenty-four species of both groups.

LAUREL is the common name of a great many very different plants, but properly belongs only to the *Laurus nobilis* of Willdenow, or sweet bay of English authors. The genus *Laurus* includes above twenty-six beautiful trees and shrubs, many of them eminently useful, and all highly ornamental. Many are natives of tropical countries, where they assume the character of lofty or timber trees; those in this country are ranked as stove-plants. The North American species are mostly deciduous shrubs, and thrive in our shrubberies. The genus was much more extensive than it now is, as the cinnamon, the cassia, the camphor, and the sweet cinnamon, were all included by Linnæus and others. The laurels and some congenerous plants are associated in the natural order *Laurineæ*, which see.

LAUREL CHERRY is the *Cerasus laurocerasus* of Loiseleur Deslongchamps, the common laurel of our shrubberies; and the Portugal laurel is the *Cerasus Lusitanica* of the same author.

LAURESTINE is the *Viburnum tinus* of Linnæus, a common ornamental plant in every flower garden. This favourite plant is easily propagated by layers, or even by cuttings with the necessary care.

LAURINEÆ. A natural order, containing, according to the last authorities, seven genera and fifty-four species of trees and shrubs bearing fine foliage, but with inconspicuous flowers. By botanists, they are easily recognised by the singular circumstance of their anthers being from two to four-celled; the valves of each are hinged as it were to the upper edge of each cell, and opening from the base upwards. The germen is free, one-celled, and the ovule solitary and pendulous. The style simple, and the stigma obtuse. The fruit is fleshy and indehiscent, often surrounded by a large persistent calyx. The seed is without albumen, and without arillas; the straight embryo large and inverted, the radicle short and superior, the cotyledons somewhat convex, fleshy, and the two-leaved plumula conspicuous.

The *Laurineæ* are divided into two sub-types: the first contains the leafy arborescent aromatic species, the second those which are leafless, herbaceous, and

insipid. The first are all aromatic plants, and exceedingly uniform in their properties. They contain essential oil in abundance, which imparts to them a peculiar sweet, though sometimes strong and penetrating odour, and a warm and pleasant taste; hence they yield some of our most grateful stimulants and spices.

The old genus *Laurus* has been divided by modern botanists, and its species arranged in three or more genera, or sub-genera, called *Laurus*, *Persea*, and *Cinnamomum*. The first includes the bay, the false benzoin, and other laurels with two-celled anthers and naked fruit. The second, the cassia, the true cinnamon, and the camphor, in which the anthers are four-celled, and the fruit covered. And the third, the alligator-pear.

Laurus nobilis, the bay, is the only European plant belonging to the type. It is aromatic, like the rest of its associates; and before the introduction of the exotic species, bay-berries and bay-leaves were much esteemed in medicine. Its use in forming crowns for heroes and scholars, has long been also obsolete, though conquerors' statues still bear a sculptured wreath of barren boughs, while the Baccalaureate degree remains a symbol that the victories of Apollo are more fruitful than those of Mars.

Laurus Borbonia is the true red bay; it yields the Isabella wood, so much prized on account of its satiny appearance, for cabinet work; and its roots afford a violet dye. *L. chloroxylon* and *L. Indica*, the green-wood and the royal bays, are both much valued for their timber; the first is hard and tough, and from its common use in machinery, is called cog-wood; the latter is light, of a yellow colour, and known as Madeira mahogany.

The sassafras of medicine is the wood of the *L. sassafras*. The alligator-pear is the fruit of the *Persea gratissima*, an excellent West India fruit. The cinnamon of commerce is procured from several species, but the best is that obtained from the *Cinnamomum verum*. The juices of *L. caustica* are highly irritating; the bark of the *L. culilaban* is the clove-scented cinnamon; and from the fruit of *L. glauca*, a concrete oil is extracted, which is used in the manufacture of candles. The other genera, in this order, are the *Cryptocarya*, *Tetranthera*, *Cassytha*, and another, which has some affinity to *Laurina*, is *Agathophyllum*.

LAVANDULA (Linneus). A genus of under-shrubs and herbs, natives of Europe. This well-known family belongs to *Labiata*. Two of the sorts are cultivated, and all are favourites, either for the beauty of their flowers, or the sweetness of their scent. The flowers and leaves of these plants have long been used as perfumes; and the ancients employed them to aromatise their baths, and to give a sweet scent to water in which they washed; hence, indeed, their generic name, *Lavandula*. The oil of *L. spica* is more pleasant than that of the other species, and is distinguished in commerce by the name of oil of spike, while the others are called oils of lavender. Sixty ounces of flowers yield only one ounce of oil; hence its high price, and the continual adulteration of the genuine drug with oil of turpentine. It contains a fourth of its weight or more of camphor, is a powerful stimulant, but its chief consumption is as a perfume; large quantities of the flowers are annually brought to London, where it is used by the citizens to perfume their wardrobes, and to expel the cloth-fretting moths.

LAVATERA (Linneus). A genus of shrubs and annual and perennial herbs, chiefly natives of the temperate parts of the world. Class and order *Monadelphia Polyandria*, and natural order *Malvaceae*. Generic character:—calyx half five-cleft; involucre of one three-lobed leaf; petals inversely egg-shaped; stamens united in a cylinder; anthers kidney-shaped; style simple; stigmas several, like bristles; capsules many, one-seeded, and disposed in a crown. The shrubby *Lavateras* are green-house plants of easy culture. The herbaceous species are mostly annuals, and are planted in the open air.

LAWSONIA (Linneus). A genus of tropical trees, belonging to the eighth class of Linneus, and to the natural order *Salicaria*. These trees succeed well in our stoves, and are propagated by cuttings. The *L. alba* is by some writers supposed to be the Gopher wood of Scripture, and is the plant that affords the celebrated henna, or al-hanneh of the Arabs. It is a curious fact that the unarmed variety should be spread over Egypt, Persia, and India, and be found even in America; while the *L. spinosa* is confined to the New World. A paste made of the pounded leaves of this plant is much used by the Egyptians, Arabs, and Turks, to dye their nails of a yellowish dark-red hue. This practice can be traced to a very high antiquity, for there is evidence that the nails of mummies have been so dyed. It does not seem that the women use henna either to heighten their own beauty, or to render their children more lovely; but rather as a mark of dignity, as slaves are forbidden to employ it. From the great esteem in which henna is held, and its vast consumption as an article of the toilet, it is cultivated expressly in Egypt for export to Constantinople, and yields the Pacha a considerable revenue. Henna is also used to dye the manes of horses, as well as to dye wool and leather. The flowers have a strong, and, to most Europeans, a disagreeable odour; but, notwithstanding their powerful hircine scent, the Oriental ladies use a water distilled from them as a cosmetic, and put them in beaupots to perfume their apartments.

LEAD. This mineral, next to iron, may be considered as the most useful of our subterranean treasures. The natural compounds of lead are too numerous to admit of a separate description; but the most important is the sulphuret, from whence the pure metal is chiefly procured.

Native carbonate of lead is one of the most beautiful of the metallic ores; it occurs crystallised and fibrous, the former being transparent, and the latter generally opaque. It is soft and brittle, and occasionally tinged green with carbonate of copper, or grey by sulphuret of lead. The octohedron is its primitive form, but it also occurs prismatic and tabular. This mineral is found in abundance both in Cumberland and Durham, and the acicular variety, possessing great beauty, in Cornwall.

The sulphuret of lead is less beautiful than the preceding, but much more extensively diffused. Its primitive form is the cube, of which there are several modifications, and among them the octohedron. The greatest quantities of this mineral are found in our own island, and in the northern parts of the continent of Europe. It may be proper to add that the greater part of the specimens of this mineral contain silver.

LEBECKIA (Thunberg). A genus of shrubs and under-shrubs, natives of the Cape of Good Hope, belonging to *Leguminosae*. They are kept in green-

house collections, thrive on a compost of loam and moor-earth, and are propagated by cuttings.

LEBIA (Latreille). A genus of small but handsome species of coleopterous insects belonging to the family *Cavabidae* and sub-family *Brachinidae*, having the elytra very broad, the thorax broader than long, with a transverse lobe on its posterior margin; the terminal joint of the palpi is larger than the preceding, with the penultimate joint of the tarsi more or less bifid. Type *Carabus cruz minor*, Linneus, a very rare and elegant British species, having a black cross upon the pale buff elytra. Bonelli separated some of the species under the name of *Lamprias*, which have linear antennæ, and the penultimate joint of the tarsi but slightly bilobed; which genus is adopted by the English, but rejected by the French entomologists.

LECHEA (Linneus). A genus of pretty North American herbaceous perennials, belonging to Linneus' third class, and to the natural order *Citineæ*. These plants, according to Sweet, are best kept in small pots, and grown in turfy loam and moor-earth. They are increased by cuttings.

LECYTHIS (Linneus). A genus of ornamental trees and shrubs, natives of South America. The flowers are polyandrious, and the genus belongs to *Myrtaceæ*. They succeed best in a rich loamy soil, and ripened cuttings produce roots in sand placed on hotbeds; the cuttings should not be stripped of their leaves. The fruit of *Lecythis* is a large pyxidium (like a chest or box) as big as a child's head, and with its operculum (opening), somewhat resembles an oil-jar, whence the generic name *L. grandiflora* is the greater, and *L. minor* the lesser, cannon-ball trees of Cumana; the former is one of the most gigantic trees in the ancient forests of Brazil. The seeds of all the species are edible, and used like chestnuts either raw or roasted: but after they are swallowed, they leave an unpleasant bitter taste in the mouth. Monkeys are, however, more fond of them than men; and hence the large seed-vessel full of seeds is called the "monkey's porridge-pot."

LEDON is the specific name of the *Cistus ledon* of Lambert. The ledon-gum rock-rose of the books and nurseries is a hardy ornamental shrub found in France.

LEDRA (Fabricius). A curious genus of homopterous insects belonging to the family *Cercopidae*, having the margins of the thorax elevated on each side into a kind of ear-shaped appendage. The type of the genus is the *Cicada aurita*, Linneus, a large and not uncommon insect in the south of England, of a dull brown colour.

LEDUM (Linneus). A genus of North American shrubs, always seen in our gardens in company with the *Azaleas* and *Rhododendrons*, brought from the same country. In America it is called the *Labrador tea*, its leaves being used as a substitute for the true *Thea* during the war for independence. The flowers are decandrious; and the *Ledums*, of which there are four species, belong to the natural order *Rhodoracææ*. The *Ledums* are raised from layers or seeds.

LEEA (Linneus). A genus of tropical shrubs named in honour of Messrs. Lee, nurserymen and botanists of Hammersmith, near London. Class and order *Pentandria Monogynia*, and natural order *Malacææ*. Generic character:—flowers monœcious; calyx bell-shaped and five-cleft; corolla tube short, limb five-cleft, segments bagged; urceolus perigy-

nous, cylindrical, in five divisions, each segment bifid; stamens alternating with the segments of the urceolus, short; anthers incumbent, style simple; stigmas thickish and gashed; berry five or six-seeded. These plants are kept in the stove, grown in light loam, and are propagated by cuttings.

LEE-CHEE, or **LITCHI**, is the *Euphoria litchi* of Desfontaines, and *Dimocarpus litchi* of Loureiro, a Chinese fruit-tree, belonging to the natural order *Sapindaceæ*. The fruit is sweet, with a sub-acid flavour, and esteemed by the Chinese. The fruit are in the greatest perfection when just gathered from the tree; and as they cannot be produced at Pekin by reason of the coldness of the climate, whole trees, it is said, are transported from Quantong to Pekin for the use of the Emperor every year.

LEEK. Is the *Allium porrum* of Linneus, a well-known culinary vegetable. The cultivation is simple; a seed bed is sown in March; soon as the seedlings are of the size of a goose-quill they are transplanted into rows one foot apart, and six inches distant from each other, upon an open rich spot of well-dug ground. They need no other care, save keeping the ground clean among them till they are fit for use. If a large size be desirable, the richest ground must be chosen for them, together with early sowing and transplanting.

LEGUMINOSÆ. One of the largest and best defined natural orders of the vegetable kingdom. It contains all the plants bearing butterfly-shaped flowers and pod-like seed vessels. Two hundred and forty-four genera are already described in books, and nearly three thousand species have been named. This order comprises some of the most useful, as well as many of the most beautiful of plants. Among the former all the products called pulse are directly or indirectly serviceable to man; and among the latter we may instance the restharrow, broom, and furze upon our wastes, up to the lupines, the erythrinas, cytisus, wistarias, and achyronias of warmer climes. Many excellent medicines are also obtained from this order, as the cassia, senna, &c. Linneus divided the pulse, which Jussieu and De Candolle have again conjoined into two orders, his thirty-second and thirty-third, called *Papilionaceæ* and *Lomentaceæ*; the first including those genera which have butterfly-shaped flowers and true legumes; the second, those in which the corollæ are regular, and for the most part rosaceous, and the fruit that modified form of legume which is known as a loment.

"The arrangement of this tribe of plants has been found to be attended with much difficulty. By Linneus, and the writers who succeeded him, the number of genera was much smaller than those admitted by botanists of the present age; many additions have been made in consequence of the discovery of New Holland, and a large number of subdivisions in the old genera have been from time to time introduced by one writer or another. To combine those scattered improvements under one uniform system has lately been attempted by the learned professor De Candolle. He has divided *Leguminosæ* into two grand divisions, the first of which consists of plants the radicle of whose seed is curved back upon the edge of the cotyledons, and the second of those whose radicle and cotyledons are straight; the former are *Curvembriæ* and the latter *Rectembriæ*. In the *Curvembriæ*, certain diversities in the structure of the calyx and corolla again divide into two principal forms; one of

which, comprehending all the genera with papilionaceous flowers, is called *Papilionaceæ*; and the other, consisting of a very small number of species, with one or two petals or more, and an obscurely lobed calyx, is called *Swarziaceæ*. The last is not subdivided, but *Papilionaceæ* resolve themselves into the two great tribes pointed out by M. De Candolle, namely, those with fleshy cotyledons and eatable pulse *Sarcolobæ*, and those with foliaceous cotyledons, and seeds which are not eatable, *Phyllobæ*. Each of these is divisible by three, upon slight differences in the fructification. In *Rectembriæ* two sub-orders, *Mimosiæ* and *Cæsalpiniciæ*, are formed upon variations in the æstivation of the calyx and corolla; in the former it is valvate, in the latter imbricated; the first constitute a single tribe, the latter into three, distinguished by less conspicuous peculiarities of structure."—Hort. Brit.

LEISTUS (Frölich; *POGONOPHORUS*, Latreille). A genus of coleopterous insects, belonging to the family *Carabidæ*, distinguished by the beautiful blue colour of the majority of the species of which it is composed, and the elongated and curiously spined lower lip; the palpi are very long, and the outside of the jaws greatly dilated at the base. The type is the *Carabus spinibarbus*, Fabricius. There are seven other British species.

LEMNA (Linnaeus). A genus of well-known aquatic annuals, belonging to the natural order *Fluviales*. There are four species, all natives of Britain, and known by the name of duckweed. These are the plants which form "the green mantle of the standing pool," alluded to in King Lear.

LEMON. Is the *Citrus medica* of Rizzo, a common and well-known exotic fruit.

LEMUR. A genus of four-handed mammalia, forming a sort of link between the apes and monkeys, and those mammalia which are without hands. The name was originally given to these animals by Linnaeus, in consequence of their habits being nocturnal, though in other respects it is rather fanciful to call them "ghosts," which is the meaning of the word lemur. As the genus was originally formed, it contained several animals differing from each other in many important characters, and as the foundation of it was nearly negative, it was of comparatively little use. Subsequent naturalists have divided the genus into three distinct parts, or indeed three separate genera—*Lemur*, properly so called, which contains several species, all of them natives of the island of Madagascar, and of that island only; *Loris*, sometimes improperly called sloths, and at other times slow lemurs, which are natives of India; and *Galago*, of which an account has been already given. We shall give a short notice of the *Loris* under that title, and confine the present article to the lemurs, properly so called. It is necessary to remark, however, that Landseer, who has given portraits of the red lemur and white fronted lemur, with his usual truth and effect, has introduced into the same plate *A. lori*, under the name of the slow-paced lemur; but the character of the animal is given with so much truth, that the trifling mistake in the name cannot mislead.

Lemurs are exceedingly singular animals, and they belong to an island of which the natural productions are altogether of a peculiar nature. It is remarkable, that though the distance between Madagascar and the main land of Africa is not very great, yet that there should be so great a difference between

both the botany and the zoology of them as there actually is. So far as is known, there is no animal in Southern Africa at all resembling the lemur in its formation and habits, neither is there any resembling the ai-ai; and as both are handed animals, and combine, with the use of hands, habits which are not possessed by handed animals in any other part of the world, it becomes impossible to apply systematic terms to them with perfect correctness. Until New Holland was discovered, Madagascar was the largest island known; and Madagascar is more related to Africa in position than New Holland is to Asia. Yet we do not find in the climate of Madagascar much resemblance to that of Africa, or in the climate of New Holland much resemblance to that of Asia. Madagascar is by far the better climate of the two, and indeed, taking all circumstances together, it is perhaps one of the best climates in the world. The cruelties which were perpetrated upon the natives by early visitors, and the disposition which the natives showed to retaliate, indiscriminately upon all nations for the wrongs which they had suffered at the hands of a few, long prevented a proper knowledge of Madagascar and its productions; but since an end has been put to the cruel traffic in human beings, and the judicious conduct of our governors in Bourbon and Mauritius has taught the people of Madagascar that there are nations to be trusted, the country has been readily opened to the footsteps of science; and the blacks of Madagascar are becoming fond of the society, the merchandise, and partially also of the science of Europe. In consequence of this, we may expect that before many years shall elapse, the production of this extensive and singularly fertile and romantic island will be well known, and its inhabitants will be added to the list of independent and improving nations.

This is a pleasing prospect in respect both of natural science and of philanthropy; and when we cast our eyes over the globe, and consider the physical state of different regions, and the moral characters, or rather the moral capacities, of the inhabitants of those regions, we invariably find that whatever of apparent fierceness and cruelty there may be in the people of a land naturally rich, there is invariably more tractability in them than in the people of a poor country; and in process of time they rise in the scale of nations, and this almost in proportion to their apparent cruelty at the time when they are first visited by more civilised nations. Taking it altogether, New Holland has perhaps the most uncongenial climate, and the most unproductive soil of any country of the same extent; while its native productions, both animal and vegetable, afford the most scanty supply of human sustenance. There is no handed animal in any part of New Holland, though there are some climbing animals, and a few supplied with membranes, which assist them in leaping from branch to branch. In the rich woods of Madagascar again, we find handed animals numerous, and several of them, such as the lemurs now under notice, peculiar to that part of the world, and also in their habits. They indicate a country which has been from the first abundant in rich forests, while the absence of handed animals in the Australian forests leads us to suppose, that the general character of very much of the surface of that extensive country must be sterile.

Now these characters are strongly impressed upon

LEMUR.

Red Lemur.

Slow-paced Lemur.

White-fronted Lemur.

the people of the new countries. Those of Madagascar resisted the visits of Europeans at the first, and they were found collected in large masses so as to be formidable; but now, while the natives have been more consolidated, they seek the intercourse of foreigners, and improve and also increase in numbers from the stimulus of that intercourse. The natives of Australia, on the other hand, though their intercourse with Europeans has been more direct and close, have not derived the same advantages from it. That they are not without capacity, is proved by the fact, that many of the children have been very forward in the schools; but it has also happened that, instead of being thereby attached to civilisation, they have almost without exception gone back to the woods, and relapsed into the habits of their fathers. The character of many of the European inhabitants, as being convicts, working in chains, or under very severe laws, must no doubt have had a pretty strong repulsive effect upon the natives of New Holland, inasmuch as men could not be expected willingly to give up a state of freedom, however precarious, in order to join a nation, the one part of which compelled the other to work in fetters, and under terror of the whip. Thus, if we still have the natives of New Holland, and more especially those of Van Diemen's Island, whose characters are a little more energetic, acting the characters of liars in wait in the bush, and indiscriminate plunderers and murderers, we, in a great measure, have ourselves to thank for it, and it is impossible to say how much this may have retarded the prosperity of our empire in that part of the world. Yet still much must also be owing to physical circumstances; and the most striking of these is the absence of handed animals, to which the peculiar handed animals of Madagascar present a very striking contrast, and would of themselves lead to the facts which we have pointed out, both with regard to the general productions of the country, and to its human inhabitants.

The lemurs are among the most remarkable of the Madagascar animals; and though they resemble the monkeys in some of their structural characters, there are others in which they approximate more nearly to the canine race. They are not, indeed, decidedly carnivorous in the formation of their teeth, nor are they furnished with claws of a formidable character; out they are nocturnal in their activity, as foxes are, and the whole of that race when in a wild state. They are also very nimble animals in all their motions; and, along with a great variety of resources, they have a great deal of tractability. They have the hand of the monkey, so that they can climb a tree with equal expedition; their legs are at the same time articulated so as to be by no means inefficient in running; and to these properties they add the scent and the sagacity of the dog. Accordingly, some of them at least are trained for the chase, and for some domestic purposes; and though there is no account of their exercising that watchfulness which must be regarded as the most valuable quality of the dog, they form better substitutes for that animal than are anywhere else to be met with. Indeed, upon looking at the plate, it will be seen that, with the exception of the hands, and the greater proportional length of the tails, lemurs have not only much of the form, but they have also not a little of the expression, of dogs.

Still, though they are employed in the chase, and though they eat animal matter, the principal adapta-

tion of their mouths is for the eating of fruits; and it is in this, and in the possessing of instruments adapted for climbing, that they bear the most resemblance to the monkeys, and are ranged next to them in the system.

In the upper jaw the lemurs have four incisive teeth, two canines and twelve grinders; but in the lower jaw there are six incisors, two canines, and only ten grinders. The upper jaw bears a considerable resemblance to that of the American monkey; while the lower jaw differs, both in the number of incisive teeth and in their form and position. They are very much elongated, very slender, and not directed upwards as in the apes, but pointing so much forward as to be nearly horizontal. The external one on each side differs in form from the others, and is so much larger that it is doubtful whether this and the one which follows it are the true canine, though that tooth is certainly not entitled to be classed as a grinder. If, however, this second tooth in the lower jaw—that is, the fourth from the front—is to be considered as the true canine, there is a difference in the mouth of the lemur from that of all animals with which we are acquainted; inasmuch as the upper canine stands farther forward than the other, whereas in other animals, the canine in the under jaw is in advance. The true grinders are all of the same form, with two points, one external and the other internal. In the upper jaw there are three grinders, of which the first is the largest and the second the smallest, the first having two tubercles on the outside very much developed. The false grinders, which are three in number, are separated from the canine by an interval. In the different species, however, there are great differences in the form of the mouth, so that it is not easy to reduce them to any general description; and the best conclusion to which we can come on an inspection of the mouth is, that the animals are very miscellaneous in their feeding. This agrees with their habits, so far as these are known, for being wholly nocturnal animals, and living in the woods, it is impossible to examine them with the requisite degree of care. Nor can we draw any certain conclusion from what they eat in a state of domestication, because they are very miscellaneous, and will eat indiscriminately fruits, farinaceous roots, insects, and animal substances.

The limbs of those animals, more especially their hind ones, are very considerably elongated; the thumbs in them are placed at a great distance from the fingers, completely free to their articulations, so that the hand forms a very efficient grasping instrument. All their fingers, or toes rather, have flat nails, with the exception of the second one on the hind foot, which has the phalanx which bears the claw very slender, and the claw itself is awl shaped. The tail is generally longer than the body, and adds much to the beauty of the form of the animal; but it is not prehensile, or capable of laying hold, which is another distinction between the lemurs and those monkeys to which they bear so close a resemblance in many respects. Generally speaking, the whole form of the lemur is slender and flexible; the head is elongated, with a triangular profile, and a slender muzzle bearing no inconsiderable resemblance to that of the fox, for which reason they have sometimes been called fox-headed monkeys. Their covering is, generally speaking, woolly, very abundant, and much frizzled out on the body; their ears are short, rounded, and covered with silky hair; their nostrils are in the

form of terminal slits; and the hair of that part of the body where they are placed more resembles that of some of the marsupial animals of Australia, than of the mammalia of Europe. The eyes are not placed looking directly to the front, as they are in man, neither are they completely lateral, but they hold an intermediate position. The mammae are two in number, and situated on the breast.

Altogether these animals thus combine the leading characters of the handed animal, with those of the quadruped. Their principal dwelling is in the trees, and they are very dexterous in leaping from branch to branch, though they do this only early in the morning, or late in the evening, as during the day they remain in a state of repose, and very generally rolled up. As they partake so much of the characters of apes, or rather of monkeys, it may naturally be expected that they also partake of the habits of these animals; but from all the accounts it should seem that they partake more of the good qualities than of the bad. They have the same ardour of character when excited, as the monkeys have; but there is far more repose about them, and they have none of those propensities which render monkeys in general both mischievous and repulsive. They are also far more docile and tractable when in a state of confinement. There is one respect, however, in which both agree, and that is the extreme affection of the females for their young; and it will generally be found that whenever this propensity is very strong, there is always a corresponding degree of ardour in the whole character of the animal. We have already mentioned that Madagascar, and we might have added the adjoining islands, are the only known localities where lemurs are natives. Several specimens of them have been brought to Europe, where they have lived, and some have produced young in menageries; but they are liable to suffer severely in the cold of the climate, notwithstanding the ample supply of fur with which they are covered.

The species of lemurs are not very satisfactorily made out, and there are sufficient reasons why this should be the case. It is but lately that their native regions have begun to be looked upon with any thing like a scientific eye; and as, from the mere fact of their being handed animals, they were long considered as belonging to the family of the apes, which gave a false impression of their general character. They are so very peculiar in their structure and habits, and so confined in their geographical distribution, that there is no doubt they would form a very valuable index to the physical condition of their native localities, if they were a little better understood than they are at present. Mammalia are from their structure much more limited, that is, much more dependent on local circumstances, than birds are, which can betake themselves to the air and range from place to place independently of the surface of the earth; and therefore, if we find any mammalia of very peculiar structure in any particular spot or distinct country, they are always the very best means we can have of ascertaining the physical circumstances of that country, and from those circumstances a general idea of its climate and productions. To do this with proper effect, it is absolutely necessary that we should perfectly understand the mechanics of the animal system, more especially the articulations of the limbs. Now though the lemur is a climbing animal, and resides for the most part in trees, it is not so exclu-

sively a tree animal as the ape, the baboon, or the monkey. These have not only the cross motion of the anterior extremities much more powerful than the motion in the mesial plane, but they have so much oblique articulation in the bones of the hind thigh and leg, and such a turning inwards of the foot upon that leg, that they get on more lamely upon the ground in proportion as they are more at home upon the tree. The baboons, many of which live where trees are thinly scattered, are better set on the legs than the apes of the close forests; and so is the chimpanzee of Africa better set on the legs than those long armed apes which inhabit the tangled forests of Java, Sumatra, and the other rich isles of the east. So also on the American continent, the spider monkeys, and the other races with very produced extremities and prehensile tails, which are found only in the closest woods, are much less clever on their feet than such species as have occasion to range from tree to tree. The structure of the lemur is different from that of any of them, and the habit agrees with the structure. Though it has hands on all the four feet, these hands are not turned on edge, neither are the joints so constructed as that the animal can turn the hand directly outwards so as to grasp a branch. Its mode of climbing is, more correctly speaking, a leaping from part to part of the tree; and thus, though it can grasp the branch upon which it more immediately rests, it cannot range over or beat all the parts of a tree in succession, in the same manner as apes and monkeys do, therefore it must be regarded as not so exclusively confined in its feeding to what the tree produces. We have said, that in some of its characters the lemur approaches more nearly to the canine race than to any other family of animals. But allowing this, it partakes also of some of the characters of the cat, not as respects its food, its method of procuring that food, or its general disposition, but as respects its organisation for motion. There is much spring and elasticity in the backbone, and the tail has that great length which is always characteristic of an animal which can leap, or which otherwise takes its motion steadily upon a definite line; and as the tail of the lemur is perhaps more produced in proportion to the size of the animal than that of any animal in which the tail is not prehensile, we may naturally suppose that it proportionally assists the animal in its function of leaping. Perhaps the nearest approximation which we have to the lemur in this respect, is in the *Ailurus* of northern India; but the *ailurus*, as may be seen by referring to that article, takes the remainder of its character as much from the cat family as the lemur does from the monkey. Indeed, before we could satisfactorily point out the proper place of these very peculiar animals in a natural system in which animals should be arranged strictly according to their organisation and geographical distribution taken jointly, we would require to bring under review all those animals to which a resemblance may be traced in the lemur; and this would be far too extended as well as too elaborate a matter for being treated of in a popular work adapted for common readers only. We shall therefore shortly notice the species as they are described by naturalists, without pledging ourselves that we enumerate the whole, that the whole are known, or that some which are described as separate species may not be mere varieties of age, or resulting from accidental circumstances.

THE RED LEMUR (*L. ruber*) is the species figured at the top of the plate **LEMURS**. It is, generally speaking, all over of a maroon red colour, with the exception of the hands, the tail, the head, the insides of the legs, and the belly, and these are black. There is also a half collar of white on the upper part of the neck. The first good representation which was given of this lemur was a drawing made by Commerçon, during his residence in Madagascar, and to whom we are indebted for many valuable truths in the zoology of that part of the world; but in consequence of his drawing not being accompanied by any description in writing, it was neglected until the return of Peron from the Southern Seas, who brought with him a stuffed skin of the animal. There was also a specimen, a female, in the collection of Mr. Bullock, in which the colours were remarkably beautiful, the whole upper part being rich maroon, and the under part, including the face and the tail, jet black; the collar had a greyish tinge, and a spot of the same colour marked the middle of each foot. There is every reason to believe, however, that the colour is subject to some variation; and the female has the white markings less distinct and pure than the male, which has sometimes caused it to be considered as a different species. It measures rather more than a foot from the back of the head to the origin of the tail, and stands nearly the same height, taken to the most elevated part of the back. The tail is more than a foot and a half in length, and, though not prehensile, has considerable power of motion. It is very easily tamed, and of the most gentle and inoffensive disposition. In its waking hours it is remarkably nimble in its motions; but it passes the greater part of the day in a state of complete repose, during which it is rolled up, with the head placed between the feet, and the tail brought over. From this habit of indolence during the daylight, it is not so interesting in a collection as one might, from its gentleness and docility, be led to suppose. Indeed it is only in their own native localities that those animals which are local and peculiar can be seen to proper advantage; and therefore, in order to form an adequate idea of the lemur, it is necessary to form some idea of a Madagascar forest, as the one is somewhat out of place without the other. The forests of Madagascar cover the greater part of the surface of the country, except where they have been cleared by artificial means. Many of them belong to the palm family, grow in the marshy grounds, and produce abundance of fruit; and the number of trees furnishing valuable timber and dye stuffs, and resins or gums of various kinds, is very great. These forests grow with great rapidity, and hide the country down to the water's edge; and as is the case in most warm climates where the rains are heavy, extensive salt marshes are formed by banks, which are thrown up by the conflicting actions of the river floods, and the sea; but in general the low grounds are so damp that the dry season tells much less severely upon them than it does in most other countries; and the consequence is, that vegetation is in a state of perpetual growth; and as it is the habit of tropical trees to bear fruit over the greater part of the year, such animals as the lemurs never suffer much from scarcity of food; and the short time in which their great activity finds their supply is sufficient to account for the indolence of their habits during the greater part of their time, for it is a law in the economy of most animals that all

those which can find sufficient food in a short time, either from their own superior powers, from the abundance of the food, or from both, pass much of their time in a state of rest or indolence.

WHITE-FRONTED LEMUR (*L. albifrons*). This species is of a reddish-brown colour in the upper part generally, with grey on the hind part of the head and the shoulders. The face as high as the eyes is black in both sexes; but in the male a band of white crosses the upper part of it, though this band does not exist in the female. The female has, however, those parts grey which are white in the male. Of the habits of this species (and it may be said of all the species), very little is known in a state of nature; and as we have already mentioned, no satisfactory conclusion can be drawn from specimens kept in a state of confinement. One which was kept in the French Museum brought forth a young one. Until it was produced, the mother was very gentle and familiar, fawning on the visitors, licking their hands, and showing many of the attentions of a dog. But no sooner was the young one produced than it occupied and even absorbed the greater part of her attention; and she became retiring and suspicious, and offered to attack those who approached her, especially if they attempted to touch the young one. As it grew up, however, her suspicions abated: and by the time that the young one was capable of finding its own food, which was at about the end of three months, all the gentleness and familiarity of the mother's character returned; clearly showing that the temporary change which had taken place in her disposition arose solely from affection for her young one, and not from any disposition to do mischief. The affection on the part of the young one was reciprocal; for on the least cause of disturbance, or even noise, it ran to its mother, and endeavoured to conceal itself in her fur.

THE MOCO OF BUFFON (*L. catta*) is one of the most beautiful species of the genus, and also one of the best defined. The epithet *catta*, which is given to it partly on the supposition of its tongue being rough like the tongue of a cat, is not correct however; for it is a smooth-tongued animal, and one which is so gentle and affectionate in its manners that it courts rather than shuns the society of human beings. The fur is reddish ash on the upper part, ash coloured on the flanks, and white on the under part; and the tail is beautifully annulated with pure white and black. There is a peculiarity in the structure of the hand of this animal, and partially also in most of the genus. The naked palm extends, though concealed in part by the hair on the upper surface, along the under surface, nearly midway to the apparent length of the fore arm; and thus the hand or paw becomes a sort of double grasping instrument, and can either hold on like a hook or act with the thumb opposed to the fingers, as necessity may require. Thus it is one of the most efficient instruments among the branches of a tree that can well be supposed, and enables the animal to climb over flexible leaves which could not be easily accomplished by means of hands of the common structure. Nor is it unworthy of remark, that in this formation of the hand there is a very considerable approximation to the mode of action, though not exactly to the form of instrument, of the sloths. This lemur, as well as some others, gets the name of *mongou*, which is indeed generally bestowed upon all those which have

more or less of brownish ash in their colouring; but it does not appear that there is any particular distinction in character or disposition that accompanies this difference of colour; and where the habits of animals are so much alike as they are in all the lemurs, mere difference of colour is of very little consequence.

THE MONGOOS OF BUFFON (*L. mongox*) is rather a questionable species, but it is usually characterised as follows—length from the hind head to the tail rather more than a foot; length of the tail nearly two feet; five fingers on all the feet, with the thumbs on the hind ones much stronger and more developed than those on the fore; all the nails are flat, with the exception of that of the first finger on the hind foot, which is a slender and pointed claw, as may be observed in the figure of the white-fronted lemur given in the plate already referred to. The nostrils are at the extremity of the muzzle, as is the case in the dog family, and there is no doubt that the sense of smelling assists the animal very much in finding its food during the night. The ears are rounded externally, and the opening is pretty large, so that the sense of hearing is also acute. The naked skin on the under side of the fingers is peculiarly delicate, and no doubt forms a very efficient organ of touch.

THE VARIEGATED LEMUR (*L. macaco*) is not very well named, because all the lemurs are varied in the colour; but this one has the colours much more varied than most of the others, by large spots of black and white. The male has the sides of the nose, the corners of the mouth, the upper part of the neck, the back, and the flanks white; and the top of the head, the belly, the tail, and the insides of the legs black, with the exception of a white bar across the middle. It is said, that in this species the young females are like the males, and afterwards changed to a different colour; which is different from most animals, as the young male more frequently resembles the female, and does not acquire the characteristic markings of his sex until he arrives at maturity.

THE DWARF LEMUR (*L. nan*) is much smaller than any of the species hitherto noticed; it is understood to be the animal which Buffon described under the name of the Madagascar rat, and which has on that account been sometimes called *L. murinus*; but it is not in any sense of the word a rat, or a murine animal of any description, unless in its being of small size, and having a long tail. In its organs of locomotion it resembles the larger and more characteristic lemurs; but its head is rounder, and its muzzle shorter, and in this respect it bears nearly the same analogy to them that the pug dog does to the fox. It is also described as being more a nocturnal animal than any of the others, with very large round eyes, and a broad muzzle, with the nostrils in advance of the jaws. The general covering is thick fur, greyish fawn on the upper part, and whitish on the under; and the face and naked skin of the hands are flesh coloured. M. F. Cuvier has described an individual of this species, the manners of which he watched with much attention. It was placed in a nest of hay, where it remained during the day rolled up like a ball, and in a state of the most profound repose, but as soon as the night set in it was all life and activity. It leaped along its cage with a rapidity equal to the flight of a bird, and it could bound vertically from the ground to the height of six feet. This last evolution is rather a remarkable one when we consider the

small size of the animal, for it is not above ten inches long in the body, nor exceeding six inches high at the shoulder. This is another instance of the necessity of guarding against confounding the muscular power or energy of an animal with the mere volume of its muscles; for this, the smallest of all the lemurs is by far the most agile and energetic of the whole.

There are various other species named by different writers, but the history of the genus is still too imperfect, and the variations of colour to which the same species is subject, are so ill made out, that some of the distinctions which are drawn are means of confusion, not of information. Years must elapse, and the very singular physical character of Madagascar and the adjoining islands, together with the working of the several monsoons upon it, must be fully investigated, before we can settle its natural history.

LENTIBULARIÆ. A small natural order, containing only two genera, viz., *Pinguicula* and *Utricularia* of Linnæus; very pretty interesting aquatics, which are with difficulty cultivated. The *Pinguicula*s are either European or North American, inhabiting elevated patches in bogs: the *Utricularia*s are floaters, found in marshes and little rills; their flowers are white, yellow, or blue. The *Pinguicula*, or butterworts, have been so called from the greasy appearance of their foliage. Like other marsh plants, they have been accused of occasioning the flukes in sheep which feed upon them. This is attributable rather to the larvæ of the fluke, or *fascicula hepatica*, which abound in marshy districts, adhering to the herbage, and thus being conveyed into the alimentary canal, than to the immediate agency of the *Pinguicula*. When mixed with cow's milk, the juice of the leaves of these plants acts like the common rennet. *Utricularia* is physiologically interesting, from the many bone-like vesicles that are developed on its immersed foliage, and which serve to float the plant. During certain seasons the *Utricularia*s are wholly submerged, and then the vesicles are full of water; but when the flowers begin to be developed, these bladders, the apertures of which are closed by a curious valve, contain only air. This is probably separated by the vital energy of the plant; and during its gradual evolution the water is absorbed or expelled, and is prevented returning, either by the mechanical structure of the valve, or by the constant evolution of air. Hence the whole plant is buoyed up, and gradually rises to the surface; the flowers then expand, the seed-vessels are fertilised, and the seeds ripened; after which the living energy of the plant flags, air no longer is secreted in the vesicles; these again become filled with water, the whole plant sinks to the bottom, and the seeds are thus sown in their proper soil.

LENTICULINA. A genus of molluscs comprising many species, all of them microscopic shells. They have been subdivided by De Montfort into so many genera, that it became necessary to consolidate the species. In their general character they partake of the formation of the *Nautilus*, being of a compressed sub-discoid shape; the centre smooth, but more generally with small knobs; the chambers not very numerous, externally visible and lying in a radiating position from the centre to the circumference of the shell's disc; some are umbilicated, others not. The derivation of the name appears to be from a little bean or grain of seed, which they may be said to resemble. Shells of this genus are frequently

found in a fossil state, but the greater number of species are recent, though but little known, and constantly overlooked in consequence of their diminutive size. On this subject we cannot resist observing, that were additional proofs required to convince the unbeliever of the infinite wisdom of the God of nature, and of the unity of purpose displayed throughout creation, these little shells would afford that satisfaction; for in them we discover analogous forms with those of the largest growth, and their diminutive tenants, each endowed with similar functions, each destined to play its part in the scheme of wisdom, and each of as much use in their sphere of action, as the elephant, whale, tiger, or other powerful animal in its predestined habits. The ingenuity of man has accomplished wonders in assisting us to see, and even study, marvellous creatures whose existence was scarcely guessed at before the perfection of optical instruments. By these much has indeed been effected, but it also leads to a safe conclusion that much more is yet to be done. Let us go on to the utmost verge of human industry, ingenuity, and rational intelligence, we can only arrive at this result—that the more man has cause to boast of his discoveries, the more he is bound to praise Him who made us what we are, and not we ourselves.

LENTIL. Is the *Ervum lens* of Linnæus, the common tare, some few of which are excellent fodder plants, others noisome weeds. Two or three of them have been used as human food from very high antiquity. Lentils, when boiled, readily dissolve into a pulpy mass of a chocolate colour; and we learn that it was for a mess of this "red porridge" for which Esau, thence called Edom, sold his birthright. In Egypt and Syria they are parched over the fire in pans, and sold as the best portable food on long journeys. They are also much used in catholic countries during lent. The London cooks prize them as an ingredient in both soups and sauces.

LENTISCUS. Is the specific name of the *Pistacia*, otherwise called the mastich tree. *P. lentiscus* is so called on account of the viscosity of its exudations. This tree affords the true mastich of commerce, which is procured by making transverse incisions through the bark, whence the glutinous juices escape; and, when inspissated by exposure to the air, are collected in the form of tears. Mastich is considered astringent and diuretic, but it is very little employed in medicine.

LEONOTIS (R. Brown). A genus of African shrubs cultivated in our greenhouses, and known by the name of lion's ear. Class and order *Didymia Gymnospermia*, and natural order *Labiata*. The flowers are showy; the plants thrive in light loamy soil, and are increased by cuttings.

LEONTICE (Linnæus). A genus of tuberous-rooted perennials, natives of the warmest as well as of the coldest parts of Europe. They belong to *Berberideæ*, and are increased by dividing the roots.

LEOPARD'S BANE. Is the *Doronicum pardaliches* of Linnæus. The flowers are showy, come forth early, and belong to *Compositæ*; are well worth cultivating, and are increased by dividing the roots.

LEPADICEA. The first family of the class *Nematopoda*, the genus *Lepas* of Linnæus, and the *Anatifa* of Lamarck. This family, as it is constituted by modern naturalists, comprises the genera *Gymnolepas*, *Pentalepas*, *Polylepas*, and *Litholepas*. These molluscs are so widely distinct from every other, that

they may immediately be discovered by their general appearance; the specific differences require more attention, and demand a closer investigation than naturalists have hitherto devoted to them. The space allotted to this subject will not permit us to enlarge to the extent necessary to gratify our own wishes; and as an eminent German naturalist has long been promising the result of his accurate investigations and laborious attention, we will not attempt to forestall his information, or give an incomplete view of it, confining ourselves at present to a general description of these singular and interesting molluscs. The animal possesses an oval formed body, more or less compressed; the mantle slit or divided at its inferior or posterior portion, though, according to the natural position of these animals, it may be termed the upper and anterior portion; the mantle is prolonged on the other side by a fleshy pedicle or stem, more or less capable of extension or contraction; this is attached to submarine bodies, and acted upon by a transverse adductor muscle. The testaceous portion is formed of five pieces or valves, squamose, or like scales touching each other more or less at their edges; one dorsal and median; two laterally anterior; and two laterally posterior; they are sometimes without any, but more frequently with numerous accessory pieces placed at the base of the shell even in the pedicle. These molluscs are invariably fixed on various floating or other submarine bodies, in very extensive groups, or thinly scattered, hanging as it were with their heads downwards, at a small depth in the sea. They appear to delight in the constant motion of the waves, which probably contributes to supply them more easily with food, which otherwise they have no mode of seeking, beyond the limited locomotion the length of their fleshy stalk permits them to enjoy. They are carnivorous, seizing their food by means of the articulated appendages with which the posterior part of their bodies is provided; these are in continual agitation, and either present a bait to the small crustaceous animals upon which they feed, or serve as feelers or smellers to indicate the proximity of their prey; and the denticulated jaws enabling them to crush, and as it were to masticate their food. It appears likely that their propagation is carried on by means of eggs, which are deposited in certain places by the assistance of a long retractile portion of the body, terminating the ovarium; and they live and die on the spot which first brought them into existence, possessing, as before remarked, no power of quitting the object to which they are affixed. In the arrangement now adopted, a very simple guide may be observed, which in the first place leads to their classification; it is the length of the pedicle, which in the first genus is very long, gradually becoming shorter in the other genera, till it ceases, and thus forms a natural transition to the *Balanides*, in which no fleshy stem or pedicle exists, the shells being firmly fixed at their base to the substance they are found upon, which a reference to the article *BALANUS* will more fully explain, and under that of *ANATIFA* we will find other interesting facts relating to the family *Lepadicea*, or genus *Lepas* of Bruguière. From the different views naturalists sometimes take, and the names they give to genera of their formation, much confusion arises, and the study of malacology is rendered additionally complex. Thus Dr. Leach constituted the genera *Otion* and *Cinearas*, now included in Cuvier's genus *Gymnolepas*; he also separated two species of

the genus *Pentalepas* into the genera *Pentalasmis* and *Poilecypede*, and in the genus *Polytepas* he separated a species under the name of *Scalpellum*. Notwithstanding the respect that is due to every thing Dr. Leach has done towards facilitating the study of natural history, we think in the present instance it is much simplified by doing away with these extremely minute distinctions, more important to the physiologist than instructive to the student. This family *Lepadicea*, and the second *Balanidea*, lead to the second class, including the genus *Chiton*, and constituting De Blainville's sub-type *Malentozoaria* or articulated molluscs. The two first families constitute the class *Nematopoda*, which answers to Cuvier and Lamarck's *Cirnepeida*; this was divided by the latter into two orders—the first, *Pedunculata*, included all of those molluscs whose bodies were supported on a fleshy stem or tubular pedicle; the second, *Sessilia*, or such species as were permanently attached, or, to use an expressive French term, *soldered* at their base, to the place in which they were born, but little objection can be made to that arrangement; we, nevertheless, give a preference to the simplicity of the classification above described, and in every branch of the study of nature we most earnestly recommend that the leading characters she constantly furnishes should guide authors in forming the true basis of every system.

LEPAS (Linnæus; CIRNEPEIDA, Cuvier, Lamarck; and NEMATOPODA, De Blainville). A class of molluscs. See LEPADICEA.

LEPIDIDIUM (Linnæus). An extensive genus of herbaceous plants, chiefly annuals, and for the most part European weeds. They belong to *Cruciferae* and are the pepperworts of English authors. The species called *L. sativa* is the common garden cress, and is a native of Persia; another called *L. oleraceum* is the New Zealand cress, also now in cultivation.

LEPIDOPTERA (Linnæus). A very extensive and beautiful order of four-winged insects, known by the English names butterflies and moths, and distinguished by having the wings composed of a double transparent membrane, clothed on the upper and under sides with minute coloured scales, resembling dust or farina. The eyes are large and lateral, the antennæ generally long and multi-articulate, and very variable in form; the mouth is composed apparently of a long and spirally coiled organ, which, when examined, is found to consist of two pieces, representing the maxillæ, sometimes being provided with a small jointed appendage or palpus at its base. This very slender and delicate proboscis (or spiritrompe, as it is called by Latreille, or antlia, by Kirby and Spence), is employed by the insect in sipping the sweets from the flowers, upon which alone it subsists, and which, by its peculiar construction, is admirably adapted for penetrating the narrowest blossoms. When at rest it is rolled up in a coil, and defended by two large and compressed palpi, composed of three joints, inserted upon a lip fixed to the front of the head. A more minute examination of the head, however, proves that the rudiments of the other parts of the mouth, namely, an upper lip and a pair of mandibles, also exist, but in a very minute state, and as it would seem, unfitted for any service in feeding—a peculiarity the more remarkable, because in the preparatory state of the larva the mandibles are very robust and horny, and constantly employed in biting the leaves, which at that time serve for the

support of the insect. The mesothorax is furnished at the sides with a pair of large scales called pterygodes (*Paraptera* or *tegulae*, vide vol. ii., p. 858) affixed at the base of the exterior wings on the upper side. The abdomen is destitute of any sting, although Dr. Burmeister has recently noticed an exotic species contained in the Royal Collection at Berlin, which appeared to be provided with an instrument of this kind, but which we should be inclined rather to regard as the acute extremity of the ovipositor, which, in many of the species whose larvæ are subterraneous or subcortical in their habits, is long and acute. The body of these insects is very pilose; it is also very variable in respect to its size; those species which are pre-eminently distinguished for their powers of flight having the body, and especially the thorax, very robust; whilst in the *Erycinidæ*, *Geometridæ*, and many others whose flight is weak, it is slender; indeed the last-mentioned family has, from this circumstance, obtained the name of slender bodies amongst the English collectors. The form of the pterygodes also is very variable, giving to the thorax a diversity of appearance; thus in the genus *Cucullia* (moths belonging to the family *Noctuidæ*) the pterygodes are very large, and the thorax is pushed forwards, forming a sort of hood over the heads, whilst in *Xyknia* they are more elongated, so as to give the sides of the thorax an elevated appearance, with the centre depressed. The colour of the thorax is generally similar to that of the anterior wings in the majority of the moths, as well as in the butterflies, in which it is clothed with fur hairs; but the prothorax often presents peculiarities of character: thus, in the larger typical butterflies, *Papilionidæ*, it is marked with two or more red or yellow spots, sometimes uniting to form a kind of collar. The wings are attached to the lateral and superior part of the thorax, and are always present; except in a few species of which the females are apterous, or have the wings reduced to small and useless appendages, the fine layers of membrane of which the wings is composed, like the upper and lower surface of a leaf, are kept expanded by a number of longitudinal corneous veins or nerves, as they have been called, but which Dr. Leach termed *Pterygostia* or wing-bones. These nerves here, as in the *Diptera* and *Hymenoptera*, according to their number and position, offer very important characters, for generic distribution, but which have been too much neglected by authors. M. Boisduval, however, in his just published *Spécies Général des Lépidoptères*, Paris, 1836, has performed good service in this branch of the science by describing and delineating the nerves of the wings of many of the species of lepidoptera; although it is proper to observe, in justice to our own countryman, Jones, that he long ago published a valuable memoir in the second volume of the Linnæan Transactions, in which the same subject was well treated. The structure of the scales, which give to the wings of these insects all their beauty, has been described in our article INSECT. The slight manner by which they are attached to the wing causes them to scale off on the least touch, so that by laying a butterfly in a reversed position on a piece of gummed paper, an exact impression of its markings will be obtained; the scales, however, being reversed, the broad extremity of each series of scales which was laid (roof-like) upon the succeeding row being hidden, and the pointed base exposed. In some species the representation will not resemble the markings of the butterfly, evidently

owing to these species having a double layer of scales on both sides of the wing, the under layer usually consisting of white scales. On denuding a wing of its scales, the points in which they were inserted are clearly to be perceived in the form of minute dots. Of the number of these scales it would be difficult to give a correct idea in the various species; Leuwenhoeck, however, states that there are more than 400,000 on the wings of the moth of the silkworm. In some species of lepidoptera, however, the wings are more or less vitreous, and consequently denuded of scales, or have but a few of them; and in others certain portions of the wing exhibit small transparent patches similarly denuded, as in the great atlas moth. In many species scales exhibit metallic tints, which, indeed, in some exotic butterflies, are so exceedingly resplendent, that in the bright light of the sun it is almost impossible to look upon them. In like manner several of our fritillary butterflies, and especially *Lathonia*, or the queen of Spain, has the under surface of the lower wings adorned with beautiful silvery spots. "How this remarkable effect of metallic lustre is produced seems not to have engaged the attention of entomologists. M. Audebert is of opinion that the similar lustre of the plumes of the humming birds (*Trochilus*) is owing to their density, to the polish of their surface, and to the great number of little minute concave mirrors which are observable on their little beards. (Nouv. Dict. d'Hist. Nat., viii. 257). But these observations will not apply to the scales of the wings of the butterflies, which are always very thin, and very flat; in some instances, as in *Morpho Menelaus*, there appears more than one very slight channel upon a scale, but this takes place also in others that reflect no lustre. Their metallic hues must therefore principally be occasioned by the high polish of their surface and the richness of their tints. It is the purity of the white, in conjunction with their shining surface, contrasted with the dull opaque colour of the under side of the secondary wings, that causes the spots that decorate those of the fritillaries to emulate the lustre of silver." (Introduct. to Ent., vol. iii., p. 652). The curious apparatus, consisting of a loop and a strong bristle, whereby the two wings on each side are retained together, is found in many of these insects, and indeed is not met with in any other order. The loop is formed either by an elevated portion of the membrane of the strong central nerve of the upper wing, or by a little tuft of raised hairs. M. Poey has observed that it is simple in the males but multiplied in the females, so that it furnishes a good character to distinguish the sexes. In our article CATOCALA we have made some general observations upon the distribution of colours in insects, whence it will be evident that it is in the day-flying species that we are to expect the greatest variety of tints; and hence it is, amongst the butterflies especially, as every one knows, that the most splendid hues and the most beautiful markings exist. Moreover it is to be observed that here, as in some tribes of plants, certain tints prevail in particular groups; thus the *Pontia* and *Pierides* are generally white; *Colias* and its allies yellow; *Polyommatus* blue; *Argynnis* and *Melitæa* yellow or buff, spotted with black, &c.; in like manner peculiar markings prevail in certain groups, so that in many cases it is easy, by merely examining a fragment of one of their wings, to ascertain the tribe of which the insect to which it belonged formed part. Thus in *Doritis* the centre of the wings have large eyes,

with red and black circles. In *Colias* the centre of the posterior wings on the inferior surface has a silvery eyelet; the species of *Danaus*, *Idea*, and *Euplexa*, have the breast and head spotted with white, and in *Acraea* the base of the wing is more or less spotted with black.

The form of the wings is very much varied, preserving, however, in the species of the various groups a certain resemblance in form; but this, however, must not be alone regarded, for amongst the strange freaks of nature we find many groups widely apart, and belonging in fact to different primary sections in the order, exhibiting so great a resemblance together, not only in appearance, but even its habits and habits, that an unaccustomed eye would be tempted to assert that the individuals formed but a single species. Thus *Geometra dealbata* flies about the foot-paths in woods, with *Pontia napi*. In the woods of Brazil, *Acraea Thaka* (a butterfly) and *Castnia acraeoides* (a moth) fly together; and in the thick forests of Guiana *Castnia linus* and *Heliconia pridi*, are confounded together whilst on the wing. In like manner *Castnia cronis* of Surinam was actually described by Cramer as the female of *Papilio cronis*. Analogies equally strong exist amongst the species contained in the separate sections; thus *Euterpe teria*, belonging to the *Pierides*, was actually placed, by Latreille and Godart, in the genus *Papilio*, to some of which, in its black wings and red spots, it bears so great a resemblance. Another and still more remote species of analogy exists between some lepidoptera and the insects belonging to other orders; thus the species of *Sesia* and *Ægeria* so much resemble some bees and wasps that they have obtained the names of wasp, hornet, and bee-sphinxes; and indeed we find such an author as Professor Bradley so far deficient upon this subject as to admit into his work a quotation to the following effect: "There are gradual alterations from a perfect moth to the bee kind; and indeed, if we examine the 26th plate, we may find a just proportion from one to the other. The antennæ of all are alike, and their bodies are just different enough to be distinguished from one another." The figures referred to representing the *Macroglossa stellularum* (the humming-bird sphinx), *Trochilium fusiforme* (the narrow bordered bee-sphinx), *Trochilium bombyliiforme* (the narrow-bordered ditto), and *Bombus terrestris* (the humble bee), of which last the antennæ are blameably made like those of the preceding insect, that they may the better correspond with the text! The species of *Ægeria* have, in like manner, received a series of names, illustrating their striking analogy with many other insects of different orders; thus we have *Ægeria Tipuliformis*, *Æger. Chrysidiformis*, &c., and the *Glaucopsis coarctata*, in the coarctate form of its abdomen, exhibits a strong resemblance to an *Ichneumon*. As to the analogies between the lepidoptera and other more distinct tribes of animals, it will suffice to state, that the humming-bird moth, and many other sphingidæ or hawk-moths, have obtained these names from this kind of resemblance, whilst some of the larger exotic moths, and especially the gigantic Brazilian *Erebus*, which measures nearly a foot across the wings, have markings on their wings, which have induced the name of *Strix* (owl) to be applied to the last-named insect; and every school-boy knows that the name owlets or owlards is given to large pale-coloured thick-bodied moths, such as the puss moth, which fly about in the twilight.

The legs of these insects are slender and hairy, offering, in many species, various remarkable peculiarities in the different sexes which have not hitherto been sufficiently examined. In general, the six legs are alike, but in some butterflies, which have thence been termed *Tetrapodes*, the fore legs are either very small or occasionally rudimental. In the majority of these insects, the only difference between the males and females consists in the larger size of the latter, and especially of the abdominal portion of the body. The colours of the males are, however, often more brilliant, and the markings more decided, than in the other sex. In some species of moths, the wings in the females are very short, and quite unfitted for flight, and in others they are entirely obsolete. Some females, in this case, also much resemble this larvæ, such as those of *Psyche* and *Oiketicus*. Various differences also exist in the colours of the opposite sexes, as in the orange-tip butterfly, of which the males have the tip of the anterior wings orange-coloured, no trace of which is to be seen in the females; or still more strikingly in the ghostmoth (*Hepialus humuli*), or the muslin moth, (*arctia neudica*), in which the colour of the wings is entirely different in the opposite sexes. Many instances have been observed, in which the same specimen has exhibited the characters both of the male and female insect, half of the body being masculine and the other half feminine; and we have seen at Berlin a specimen of the scarce egger-moth, which was actually quartered in this manner, the front part of the body and front wings being half male and half female, and the hind part and hind wings half female and half male. M. Andersegg, a Swiss entomologist, has also observed a specimen of *Setina*, which exhibited not only hermaphroditism, but also hybridism, one side being that of a male, *S. ramosa*, the other a female, *S. aurita*.

These insects undergo the ordinary transformations to which insects are subject, being produced from eggs, and appearing as caterpillars, after which they become pupæ or chrysalides, and finally arrive at the perfect state; but as we have already, in our articles *INSECTS*, *CATERPILLAR*, *COCOON*, *CHRYSLIS*, and *BUTTERFLY*, described these various states, we shall now content ourselves with a short notice of the chief modes of distribution of the insects.

In the earlier editions of the *Systema Naturæ* Linnaeus adopted only two genera; namely *Papilio* for the butterflies, and *Phalæna* for the moths. In the last editions, however, he added a third genus, *Sphinx*, and subdivided these three groups in the following manner:—

1. *Papilio*. Antennæ clavate.
 - A. *Equites*.—Posterior margin of the wing longer than the anal margin, divided into Trojans, having red spots on the breast, and Greeks having no spots.
 - B. *Heliconii*.—Wings narrow, entire, often almost naked.
 - C. *Danai*.—Wings entire, divided into the *Candidi* or whites, and *festivi* or variegated.
 - D. *Nymphales*.—Wings dentated, divided into the *Ocellati*, or those with eye-like spots, and the *Phalerati*, or those with simple spots.
 - E. *Plebei*.—Caterpillars, short, thick—divided into the *Rurales*, or those with dark spots, and the *Urbicolæ* with transparent spots.
2. *Sphinx*. Antennæ prismatic, thickest in the middle.

3. *Phalæna*. Antennæ setaceous, often feathered, divided into

- A. *Attaci*.—Wings somewhat extended and inclined at rest.
- B. *Bombyces*.—Wings crossed upon the body, antennæ pectinated.
- C. *Noctux*.—Wings crossed upon the body, antennæ setaceous.
- D. *Geometræ*.—Wings horizontal.
- E. *Tortricæ*.—Wings very obtuse, front margin curved.
- F. *Pyrales*.—Wings forming with the body a furcate delta.
- G. *Tineæ*.—Wings rolled into a cylinder.
- H. *Alucitæ*.—Wings digitated.

Latreille adopted the Linnæan groups, to which he gave the names of—1. *Diurna* (day fliers). 2. *Crepuscularia* (twilight fliers); and 3. *Nocturna* (night fliers). This mode of primary distinction has also been adopted by Mr. Stephens; by whom, however, a distinct mode of classification of the *Nocturna*, or Linnæan *Phalæna*, has been proposed, and by whom the following groups, considered as of equivalent rank with the *Diurna* and *Crepuscularia*, have been formed.

1. *Lepidoptera pomeridiana*, corresponding with the Linnæan *Bombyces*, and comprising four families: *Hepialidæ*, *Bombycidæ*, *Notodontidæ*, and *Arctidæ*.

2. *Lepidoptera nocturna*, corresponding with the Linnæan *Noctux*, and comprising two families, *Lithosiidæ*, and *Noctuidæ*.

3. *Lepidoptera semidiurna*, corresponding with the Linnæan *Geometræ* and *Pyrales*, and comprising the families *Geometridæ*, *Platyptericidæ*, and *Pyralidæ*.

4. *Lepidoptera vespertina*, corresponding with the Linnæan *Tortricæ*, *Tineæ*, and *Alucitæ*, and comprising the families *Tortricidæ*, *Yponomeutidæ*, *Tineidæ*, and *Alucitidæ*.

There are still two other very valuable works upon the lepidoptera, of the mode of distribution of which we would have given an account; their incomplete state, however, prevents our doing this. We allude to Dr. Horsfield's *Lepidoptera Javanica*, and the before-mentioned work of M. Boisduval; the former of which, by its philosophical introduction, and the latter by the careful description of all the species of this order, which it will contain, are especially deserving of attention. The British species, of which there are nearly 2000, have been described by Mr. Stephens in his *Illustrations of British Entomology*, and by the late lamented A. H. Haworth in his rare *Lepidoptera Britannica*.

LEPISMA. Linnaeus. A genus of apterous insects, belonging to the order *Thysanura*, Leach, and family *Lepismidæ*, having the body more or less compressed, and posteriorly attenuated with a double series of lateral moveable appendages or false legs on the underside of the body, and the anus furnished with three filaments. The thorax is composed of three segments, each bearing a pair of legs; the antennæ are long and setaceous. These insects are of small size, and are clothed with a fine silvery kind of small scales, which give the body a glittering appearance. They run well, and some species leap to a considerable distance by means of the anal appendages, whence they have obtained the names of spring-tailed insects. They are chiefly found under stones in damp situations, in moss, &c. The sugar louse,

also, a small and very agile species, found in casks of sugar, is also a member of this group, and is termed *L. saccharina*. (See the Transactions of the Entomological Society, Vol. I., for a Monograph upon the *Thysanura* of Ireland, by R. Templeton, Esq.)

LEPTIS (Fabricius). A genus of dipterous insects, belonging to the family *Rhagionidæ*, having the antennæ as long as the head, with the basal joint elongated and cylindrical; the second short, the third conical, the palpi turned upwards; the posterior tarsi thicker than those of the anterior legs, and the abdomen linear. The type is the *Musca vermileo* of Linnæus, an insect having somewhat the appearance of a moderate sized *Typula*. Its larva is cylindric and fleshy, with the anterior part of the body much attenuated. It resides in sandy places on the continent, where it forms a burrow, at the bottom of which it hides itself, sometimes concealing itself entirely, and sometimes partially, and seizes upon any insect which may happen to fall into the hole, round which it writhes itself like a serpent; it then pierces its skin with the sharp setæ with which its mouth is furnished, sucks its juices, and then by a sudden motion of the body, similar to that made by the larva of the cheese-fly, throws it aside. The pupa is enclosed in a cocoon of sand.

LEPTOSPERMUM (Forster). An interesting genus of evergreen shrubs from New South Wales. The flowers are icosandrious, and belong to *Myrtacæ*. Generic character: calyx turbinate, limb five cleft; petals five, inserted into the calyx; stamens fixed in the throat of the calyx, shorter than the petals, style filiform, stigma headed; capsule four or five celled, cells full of seeds. The *Leptospermums* are grown in sandy loam and moor-earth, and increased by cuttings of the young shoots.

LEPTURIDÆ. A family of coleopterous insects, belonging to the section *Tetramera*, and sub-section *Longicornes*, having the eyes entire and rounded, or but very slightly emarginate, with the antennæ inserted in front of them, or at least at the outer extremity of the emargination, and never within the eye itself, as in the *Cerambycidae*; the head is always bent downwards, and prolonged behind the eyes into a sort of neck. The antennæ are moderately long, and the abdomen is gradually attenuated towards the tip. This is a family of considerable extent, comprising many handsome species, forming the Linnæan genus *Leptura*. They are found in the spring and summer months in flowers, especially those of the whitethorn and umbelliferæ; they fly well in the sunshine. Their larvæ are found in rotten trees, upon the bark of which the perfect insects are also often to be seen. There are thirteen genera in this family described by M. Serville in his Monograph contained in the *Annales de la Société Entomologique de France* for 1835, including *Rhagium*, *Torotus*, *Pachyla*, *Gramoptera* (*Lept femorata*, *ruficornis*, &c.). *Leptura* and *Strangalia* (*L. calcarata vel elongata*), examples of all of which are found in this country. The typical genus *Leptura* is distinguished by the elongated body, attenuated from the base to the extremity of the elytra; the antennæ eleven jointed; the thorax unarmed at the sides, and broader behind than before. The type of the genus is the *L. melanura*, Linnæus, a common British species.

LESPEDeza (Michaux). A genus of perennial plants, chiefly herbaceous, belonging to *Diadelphia*, and natural order *Leguminosæ*. Many of the species

are hardy; some of them receive the protection of the greenhouse, are increased by cuttings, and succeed with the ordinary management.

LESSERTIA (De Candolle). A genus of undershrubs, herbs, and annuals, natives of the Cape of Good Hope. They belong to *Leguminosæ*. They are grown in loam and peat-earth, and may be raised from cuttings or seeds, which are sometimes produced in abundance.

LESTEVA (Latreille; *ANTHOPHAGUS*, Gravenhorst). A genus of coleopterous insects, belonging to the family *Stephylinidæ*, and remarkable for the resemblance which some of the species exhibit to the smaller *Carabidæ* with truncated elytra, whence the type of this genus has been named *L. caraboides*. They are of small size, and are found under stones and moss in damp places.

LETHRUS (Scopoli). A genus of coleopterous insects belonging to the *Lamellicornes*, and family *Geotrupidæ*, having the terminal joints of the antennæ formed into a reversed conical mass; the head is very large, as well as the mandibles, which in the males are armed with a strong curved tooth; the abdomen is very short and semicircular. These insects, of which there are several species, the type being the *L. cephalotes*, Fabricius, inhabit Hungary and Western Russia, where, according to Count Gotth. Fischer de Waldheim, this species is very injurious, devouring the tender shoots of various plants, and especially of the vines, which it bites off with its powerful jaws, and drags backwards into its narrow burrow in which it resides together with its partner. During the season of coupling, a strange male will sometimes make his appearance at the mouth of the hole, when a violent battle ensues, which ends only with the death or flight of the intruder. The celebrated Russian entomologist above mentioned, has described several new species of this curious genus in his splendid *Entomographia Russia*, vol. I, part xiii.

LETTUCE. See *LACTUCA*.

LEUCADENDRON (Linnæus). A numerous genus of evergreen shrubs, natives of the south of Africa. Class and order *Diacia Tetrandria*, and natural order *Proteacæ*. These plants require to be placed in a compost of light loam and moor-earth, with the pots well drained, as they are liable to suffer if overwatered.

LEUCOJUM (Linnæus). A genus of bulbous perennials, chiefly European. They belong to the sixth class of Linnæus, and to the natural order *Amaryllidæ*. The English name of these plants is snow-flake, from the flowers of one of the species appearing early, shaped like those of the snow-drop. Another species, a native of England, flowers in the beginning of summer, and is then very conspicuous. Increased by offsets.

LEUCOSPIS (Fabricius). A genus of hymenopterous insects, belonging to the family *Chalcididæ*, of which they constitute the largest species, and are distinguished by the singular position of the ovipositor, which, when unemployed, is laid along the back, sometimes extending as far as the scutellum. These are handsome insects, varied with yellow and black, and inhabit the middle and south parts of Europe, America, Asia, &c. There are about thirty species known.

LEUZEÄ (De Candolle). A genus of herbaceous plants, chiefly European. They belong to *Compositæ*, and were called *Centaurea* by Linnæus.

A light flower border is suitable for them, and they are increased by seeds or dividing the roots.

LIATRIS (Gærtner). A genus of North American herbaceous plants, belonging to *Compositæ*. Several species are in our flower gardens, and esteemed handsome. Some of them have this peculiarity, that whereas most other plants having a spike of flowers, blow from the bottom upwards; this blooms first at the top, and successionally flower after flower downwards. They are propagated by slips and by seeds, which should be sown as soon as ripe.

LIBELLULIDÆ (Leach). A family of neuropterous insects, comprising the dragon-flies, or genus *Libellula* of Linnæus, distinguished by the minute size of the antennæ (whence they form with the ephemeræ the group named *Subulicornes* of Latreille), and the large size of the mandibles. Having in our articles DRAGON-FLY and INSECT (vol. ii. p. 847), given various details relative to the natural history of these insects, it only here remains for us to notice the mode in which the Linnæan genus has been divided by recent authors. Fabricius introduced two additional genera, *Æschna* and *Agriion*, and Dr. Leach divided the Linnæan group into two families, *Agriionidæ*, which see, and *Libellulidæ*; in the latter of which the wings are horizontally extended when at rest. He also proposed the additional genera, *Anax*, *Cordulia*, *Cordulegaster*, and *Gomphus*, all of which are British, founded upon the form of the wings, and of the abdomen and anal appendages; the typical genus *Libellula* (having for its type the *Libellula depressa* of Linnæus), having the posterior wings alike in both sexes, and the abdomen more or less depressed. The typical species above mentioned is a large and handsome insect, often to be seen in the summer hovering over stagnant water; the abdomen of the males being of an opaque blue colour, and that of the females dark fulvous brown; the wings have a large dark patch at the base.

LICHENES. Is a natural order of Jussieu's second grand division, *Cellulares*. There are thirty-five genera and four hundred and twelve species already described, and no doubt many more remain to be discovered. The lichens are useful in the economy of nature in preparing the surface of the earth for the reception of larger vegetables. Some few of them are eatable, others are used by the dyer, and several are medicinal. Various species appear as the weather-stains on old walls; they cover desert wastes, or mottle the bark of ancient trees.

LICINUS (Latreille). A genus of coleopterous insects, belonging to the family *Carabidæ*, sub-family *Harpalidæ*, having the last joint of the palpi large and hatchet-shaped, the mentum without a central tooth, and obtuse mandibles; the body is broad and depressed, and the species are of black colours. Three only are found in England, *Carabus silphoides* of Fabricius being the type.

LIGHTFOOTIA (Le Heretier). A genus of undershrubs, natives of the Cape of Good Hope, belonging to *Pentandria monogynia*, and to the natural order, *Campanulaceæ*. Generic character: calyx of five sepals; petals lance-shaped, stamens, filaments dilated at the base, and forming a hollow; stigma from three to five-cleft; seed-vessel three to five-celled. Succeeds with the ordinary green-house management.

LIGULUS. A genus of molluscs constituted by

Dr. Leach, but now forming a subdivision of the genus *Lutricola*.

LIGUSTICUM (Linnæus). A genus of large herbaceous perennials, natives chiefly of Europe. The flowers are pentandrous, and the genus belongs to the order *Umbelliferae*. The common sort is cultivated in gardens under the name of lovage, used as a potherb, and propagated by seed.

LIGUSTRUM (Linnæus). A genus of two species, and of one of which there are several varieties. Class and order, *Decandria monogynia*, and natural order, *Oleinae*. The common privet is a native of Britain, and one of its varieties is an evergreen, and much in repute for thickening shrubberies and forming evergreen hedges for shelter or ornament. *L. lucidum*, the Chinese privet, is rather a tender plant, and requires a sheltered situation; both are easily propagated by cuttings or layers.

LILAC. Is the *Syringa vulgaris* of Linnæus, of which there are four varieties in our shrubberies. Two other species ornament our gardens, namely, the Chinese and the Persian: of the latter there are two or three varieties. They are all easily propagated by layers or suckers from the root.

LILIUM (Linnæus). A splendid genus of bulbous flowering plants, belonging to the sixth class of Linnæus, and to the natural order, *Tulipaceæ*. Generic character: corolla bell-shaped, regularly six-parted, segments spreading and reflexed, with a nectariferous furrow down the centre; stamens inserted into the base of the corolla; anthers versatile; style columnar; stigma three-lobed; capsule three-sided, six-furrowed, three-celled, three-valved; valves united by a fibrous net; seeds compressed. The *L. candidum*, the white lily, stands deservedly at the head of the genus: and nothing shows more decidedly the estimation in which it is held, than that it is seen in almost every cottage garden. The superb, the chalcidonian, and the tiger species, are all equally valued; indeed, the whole of the twenty-six species are highly ornamental, and easily increased by offsets from the bulbs. They affect a light rich soil; but the North American species do best in moor-earth.

LILY OF THE VALLEY. Is the *Convallaria majalis* of Linnæus. A British plant so much admired, as to be seen in every garden.

LIMAX (Linnæus, and modern authors). This mollusc is so well known as the common slug of all countries, that a description of it would here be useless merely to point out its general character; but as it is one of those unfortunate animals whose appearance inspires mankind with disgust, and renders it an object of persecution and destruction, few of our readers would probably be tempted to examine it minutely for his instruction, or deem it worthy of attracting any portion of his admiration. We shall, therefore, give a more particular description of its wonderful structure than so humble an inhabitant of this planet may appear to deserve; we would also gladly awaken sentiments of compassion towards it, upon the principle we have attempted to establish with regard to its neighbour and relative, the common snail. The body of this terrestrial mollusc is an elongated, oblong, oval form; it is completely gastropod, or crawling on its belly, possessing no externally formed legs, but progressing in its motion by means of certain internal muscles, so arranged as to give a fixed reliance on each in succession, as the advance or step forward is made, from the first seg-

ment of the body to all the others; and in certain situations where the ground is ill adapted to the animal's locomotion, a slimy juice is expelled from its body to smooth the path, or give an additional hold to its footing. The skin of the slug is very thick, but more particularly at the anterior part of the back, where it forms a sort of fleshy fold or shield, extending more or less over the sides of the animal's body; in the interior of this is contained a rudiment of shell in the shape of a small detached flat osseous substance in some species, and in others there are only corpuscular grains or elementary parts of bone to be discovered; these are not exhibited on the exterior, but doubtless tend to guard the pulmonary cavity which lies on the right side immediately beneath this shield or fleshy cowl. The animal has four tentacula, retractile, and capable of considerable extension; the larger or posterior pair are furnished with eyes at their summits; these, with the other tentacula, assist as feelers to avoid danger, and are probably furnished with organs of smell to guide the animal to its food, its visual faculties appearing extremely limited. These tentacula constitute an important part of the animal's economy of structure, so much so indeed that nature is said to renew them when they have been destroyed by accident or philosophical cruelty; the fact does not, however, rest upon any confirmation of our own, though it is corroborated by analogous circumstances in other molluscous animals, which leave but little doubt of its truth. Abundant as these molluscs are, they are difficult to separate into species, and only a few appear to have been distinctly characterised by naturalists; their habitat is also equally general, as they are found in the tropical and northern hemispheres, where, like the snail, they perform the functions of their existence with greater advantage to mankind than they receive credit for. Had our limits permitted, we should have been pleased to have had an opportunity of carrying on this article to a somewhat greater extent by endeavouring to trace the interesting chain which evidently connects the *Limax* or common slug, in which the portions of testaceous matter are merely elementary to other molluscs, in which they become small tabular pieces—a solid crustaceous substance, a small well-defined shell, partially covering the branchial cavity of the animal's body, and finally a perfect shell, serving as a defence and retreat for the entire body of the animal; these connecting links may be traced in the *Parmacella*, *Testacella*, *Onchidium*, *Dolabella*, and *Vitrina*, till we arrive at the *Helix*; or pursue the reverse course, and trace the links from the perfect *Helix* down to the *Limax*, which seems to be the more natural arrangement. In throwing out this suggestion we will lend our assistance, by describing minutely each of the genera we have named as bearing on the question, and to the best of our judgment draw just conclusions by analogous reasoning in those instances where we cannot obtain information from actual observation or the well authenticated researches of competent naturalists.

LIMACINA (Cuvier; **CLIO** **HELICINA**, Linnæus). Gmelin called this genus of molluscs *Helicina*, which appears more descriptive of its general characters; but the name of *Limacina*, given by Lamarck, has been adopted by succeeding authors. In many respects it approximates to the genus *Planorbis*, particularly in having a very wide umbilicus, formed by the flat spread of the whorls. The shell is thin, fragile,

and papyraceous; its whorls spiral as in the common *Helix*, but united in a discoid form. The body of the animal is of an oblong form, with two branchial fins situated at the base of the neck; the posterior part of the body spiral. This genus differs in few particulars from the Linnæan genus *Clio*; the animal, however, possesses the power of retreating completely within its shell, which is not the case with the *Clio*. The *Limacina* inhabits the North Seas, and is classed by Lamarck as the second genus of the fifth order *Pteropoda* or winged feet. De Blainville has called this genus *Spiratella*; he observes that the characters were taken from Captain Scoresby's Voyages, and are established on an almost microscopic animal found in the Arctic Seas.

LIMACINEA. The third family of the first order *Pulmobranchiata*, first class *Cephalophora*. It includes the genera *Succinea*, *Bulinus*, *Achatina*, *Clausilia*, *Puppa*, *Anastoma*, *Helix*, *Carocolla*, *Helicolimax*, *Testacella*, *Parmacella*, *Limacina*, *Limax*, and *Orchidium*. The form of the animal is very various: the head, provided with two pairs of tentacula, completely retractile within the animal's body, the posterior pair larger than the other pair, and bearing the eyes at their extremities; one tooth on the upper lip; the tongue or lingual mass is small, and covered with a skin thickly set with microscopic teeth or bristles. The shells of these genera, which constitute the family *Limacinea*, are as different in their form as the animals inhabiting them, the one occasioning the other, but their general characters never vary; in many respects, such as being always spiral, of an oval or globular form, more or less discoid or compressed; the summit of the whorls smooth, always without an epidermis; the aperture round, semilunar, oval, or angular, but never notched. The animals inhabiting these genera are all terrestrial, and feed on vegetables generally, such as fruit or other soft substances which admit of being reduced by the action of the tongue in licking them. The garden snail in this, as well as many other instances illustrative of the structure and habits of a considerable portion of molluscs, may constantly and easily be seen; and a reference to the article **HELIX** will further explain some of the daily habits of all similarly constructed animals. The great number of terrestrial molluscs that exist in every climate, and their beauty and usefulness in almost all countries, have excited considerable interest, and occasioned consequently many ample and minute descriptions of their species. Several eminent naturalists have attempted a general classification, in which, however, a contrariety of opinion must ever exist; but the late Baron de Ferussac appears to have reconciled most of the disputed points. His splendid work on Terrestrial Molluscs must ever be viewed as a masterly and elegant production, and will be handed down to posterity a monument worthy of his great name as a profound naturalist, enlightened scholar, and amiable man. In the genera contained in this family, we have preserved in our order of enumeration the usually received arrangement of modern naturalists, without disputing its general excellence; and in such instances as have occasioned a slight difference of opinion, we have frankly expressed our reasons for dissenting from such high authorities, not in a spirit of self-sufficiency, but rather to throw out an useful hint by which the difficulties now surrounding the study of malacology may in some degree be lessened, and a lure held out to our readers to

mark, learn, and reason for themselves; for if they would become proficient in natural history, they must read the book of nature in her own deeply traced and undeviating characters of truth and infinite wisdom.

LIMA (Bruguière, Cuvier, Lamarck; *OSTREA LIMA* of Linnæus). A genus of molluscs confounded by old authors with the *Ostrea*; a separation from them, however, is manifestly correct, as the animal has become well known, and is ably described by recent authors. Its body is slightly compressed; it has a byssiform abdominal appendage; the edges of the mantle are furnished with several rows of tentacular cirri; the mouth surrounded by a thick lip, with a fringed edge. The shell is equivalve, oval, more or less oblique, gaping at the anterior part of the lower side, the summits anterior and distant, the hinge longitudinal, without teeth, and the ligament rounded, nearly external and inserted in a cavity on each valve. The muscular impression is central, and distinctly divided into three portions; the ears at the base are very small, but quite visible; the colour of the valves is a delicate white. Some species are more ventricose than others, but they all possess longitudinal ribs armed with vaulted scales, imbrications like a rasp, whence its name, or with striæ; the margins are crenulated, and closely interlock when the valves shut. Lamarck enumerates six species, inhabiting India, America, Australia, and the Mediterranean; and many fossil species are known. It is of the second family *Subrostracea*, third order *Lamelibranchiata*, class *Acephalophora*.

LIME is the *Citrus limonum* of Rizzo, a useful fruit-tree indigenous in India, and cultivated in many other parts of the world, for its juice which is so useful in medicine, and many domestic and culinary purposes. The wild lime is probably the original species whence has been obtained all the fine varieties of this valuable family.

LIME TREE is the *Tilia microphylla* of Linnæus. The genus are European and North American timber trees, very commonly used in ornamental planting, for forming avenues, open groves, and form handsome objects when planted singly on dressed ground. The timber is soft, very white, and chiefly used in turnery. All the sorts may be readily propagated by layers.

LIMNIIDÆ (Stephens). A family of small aquatic *Coleoptera*, belonging to the section *Pentamera*, and sub-section *Philhydrida*, distinguished by having the antennæ nine or eleven-jointed, filiform, or but slightly thickened towards the tips, and as long as the head and thorax; the legs are furnished with two very strong claws, and the last joint of the tarsi is very long. The British genera are *Limnius*, Illiger (or, more properly, *Elnis*, and hence the family name should be changed to *Elnidæ*), and *Georyssus*. The species are small, and although residing in deep and running water, they are not formed for swimming; but still we find their legs, and especially their large tarsal claws, admirably adapted for retaining firm hold of the tough under-surface of stones, beneath which they are always found. There are twelve British species of *Limnius*, and one of *Georyssus*.

LIMNACEA. The first family of the first order *Pulmobranchiata*; second class *Paracephalophora*. All the molluscs included in this family are inhabitants of fresh water rivers, or stagnant pools, frequently merely floating on the surface, and sometimes

at the bottom. The form of these shells vary considerably; but the substance of the shell is constantly thin, and the external edge always sharp. Most of them being within our daily reach, a very minute description of them here is not necessary.

The shape of the animal constructing these molluscs, varies as in every other instance. Their general characteristics are, in many respects, similar to the family *Limacinea*. They have, however, only one pair of completely retractile flattened tentacula, upon which the sessile eyes are situated on the internal side of their base. They are amphibious, usually without an operculum; but the aperture, under some circumstances, closed by a thin calcareous cover. The genera included in this family are *Lymnaea*, *Physa*, and *Planorbis*. They are abundantly found in all countries; each genus containing numerous species, particularly that of *Planorbis*.

LIMNOCHARIS (Bouffand). An aquatic genus of plants, natives of Brazil, belonging to *Polyandria monogynia*, and to the natural order *Hydrocharidæ*. Generic character: calyx of three sepals; corolla of three small petals; stamens inserted into the receptacle: capsules several, one celled, and many seeded. This is grown and readily flowered in our stoves in tubs of water. The organisation of the leaves is curious: at the point of the costa or midrib of the leaf, there is an aperture whence pure water appears to be distilled in globular drops. The *L. plumieri* is only a biennial; and, therefore, to preserve the plant, seeds should be saved.

LIMNORIA (Leach). A genus of minute but very destructive crustaceous insects, belonging to the order *Isoptoda*, and family *Cymothoidæ*, having the eyes granular, the antennæ four in number, and inserted nearly in a line, and four-jointed; the legs similarly formed and fit for walking; the abdomen six-jointed, the last segment being large and suborbicular. The only species is the *Limnoria terebrans*, which does not exceed one-sixth of an inch in length, but which, from its wood-eating habits and great powers of multiplication, is one of the most destructive of our insect enemies, attacking piles of wood immersed in the water, in our dock-yards, flood-gates, timber bridges, chain piers, &c., and which in a very short time it completely perforates in a most alarming manner, boring to the depth of several inches in every direction. It is found in many parts of the coast, both of Great Britain and Ireland (see Thompson and Coldstream in the Edinburgh New Philosophical Journal, 1834), and France. From Coldstream's elaborate paper just referred to, it is evident that the boring of this little insect in the wood has for its object the obtaining a supply of food, as "the contents of the stomach resembled comminuted wood," and that it commences its ravages on an entire piece of wood, by fixing upon the soft parts situated between the harder annual layers, and by subsequently working upwards at an angle of 45°, keeping in preference in the course of the soft layer into which it bored at first; the mandibles appear to be its chief tools; it likewise appears necessary that the hole should be filled with salt water whilst the insect is at work. Very often, however, the galleries are horizontal, and sometimes perpendicular, the walls being as smooth as if cut by a sharp knife. With a view, however, of more particularly calling the attention of scientific persons, and especially those whose knowledge of chemistry may best enable them to suggest prac-

ticable remedies against the attacks of this pest, we will notice more precisely the extent to which the damage caused by it has extended in some of our public works, our information being condensed from Mr. Coldstream's paper. During the building of the Bell Rock Light-house, it was necessary to erect a temporary wooden building, in which the engineer and his assistants resided, and which was supported by twelve large beams of Memel fir fixed in bolt holes cut in the rock; the sides of these beams were charred and pitched, but the bottoms, which closely fitted to the holes, were left naked. In the second year the edges of these timbers were in a state of decay, owing to the borings of the *Limnoria*. The logs of Norwegian pine laid down to support the temporary railways were also very much destroyed: the timbers, which were at first ten inches square, being reduced in four years to seven inches; that is, losing at the rate of one inch per annum. In several instances, also, the house timbers were so completely eaten away at the bottom, that they stood clear of the rock, supported only by the bolts and stanchions. The piles supporting the timber bridge at Montrose "were very much destroyed by the borings of the same animal, so that the stability of the whole structure was seriously endangered;" and in like manner the piles supporting the Trinity Chain Pier at Leith were in 1825, four years only after their first fixture, found to have been so very much destroyed by the *Limnoria* as to be useless, and they were at a great expense removed and replaced by new ones; the girth of some of them which were originally forty-eight inches in circumference, having been reduced to six inches, so that the least force was sufficient to break them through. The attention of scientific men became at length seriously aroused; various plans for remedying the mischief were proposed and tried; but none succeeded so well as covering the whole surface of the pile, from the place where it met the bottom of the sea to within a foot or two of mean high-water mark, with broad-headed iron nails, technically called scupper nails, set close together; the taste of wood, now encrusted with a thick coat, as well as impregnated with oxide of iron caused by the presence of the nails, probably offending the taste of the *Limnoria*. Thus a piece of wood covered on three of its sides with the scupper nails was found to have the whole interior eaten away, so much of the exterior only being left as had been penetrated by the nails on the sides. This plan was adopted at an expense of about 1000*l.* in the Leith pier, which cost 30,000*l.*, and after four years, it was discovered that none of the piles thus protected had been penetrated by the *Limnoria*; whilst some wood work attached to the pier, but not so defended, is now much destroyed. It is essential, however, to watch the condition of the piles from time to time, even though covered with the iron nails, because the heads of the nails frequently fall off after being much oxidized; and it is very possible that the coat of oxide which they have previously communicated to the pile may also be abraded so as to leave the wood entirely exposed to the enemy, and the nails which fall away ought to be replaced by new ones as fast as possible. We cannot take our leave of Mr. Coldstream's paper without quoting at length his admirable and truly philosophical observations upon the purposes which the *Limnoria* is fitted to serve in the economy of nature, and which it will be seen correspond in some

NAT. HIST.—VOL. III.

respects with the remarks which we made upon the injuries arising from the attacks of insects in our general article INSECT. "Although the destructive agency exerted by this minute animal be forced upon our attention, chiefly by its ravages in works of great practical utility, and therefore cannot at first view be regarded by us with complacency or admiration; yet, upon further reflection, we must be convinced that the purposes which the *Limnoria* is fitted to serve in the great plan of the creation, are such as could be accomplished by no other living creature with which we are acquainted, and that they are calculated to contribute in no small degree to the comfort and well being of man. Let us consider, for instance, how possible it is that large trees or masses of wood floated down by rivers might accumulate on shoals at their mouths to such an extent as materially to diminish the outlet for the waters, which then would rise and overflow their banks, were it not for the destructive boring of the *Limnoria*: what could not be accomplished by the brute force of any marine animal, and might baffle even the ingenuity and power of man himself, is yet quietly accomplished by the gradual but steady operations of a tiny crab."—"Nor must we omit to notice the possibility of its being the means occasionally of causing the removal of those serious obstacles to the safe navigation of shallow seas, which are caused by the masts of sunken vessels. But whether we be right or wrong in our suppositions as to the use it may be of in the economy of nature, we cannot be mistaken in regarding the ravages of the *Limnoria* as showing what formidable enemies to man the Creator can prepare, even amongst what appear to us the most insignificant of His works, and how He, who ruleth over all, effects important purposes, by means of the smallest and apparently most incompetent agents."

We must also refer to a paper by the Rev. F. W. Hope, contained in the second number of the Transactions of the Entomological Society, in which several useful remedies are suggested; and we would also notice the probability, that the immersion of wood to be employed in submarine works in Kyan's patent solution, would also be very serviceable.

LIMULUS (Fabricius). A curious exotic genus of Crustacea, constituting the sub-order *Xyphosura* (see article CRUSTACEA), and known by the common name of king crabs, having the body covered by a large and nearly rounded shell, divided into two parts, the anterior being large and semilunar, and the posterior toothed at the sides, and deeply notched behind, and terminated by a very long and acute spine; the mouth is not provided with any sucker, the coxæ of the six anterior pairs of legs being dilated and spined, and performing the office of jaws; the anterior pair of legs is very short, and seem to serve as a pair of claws assisting in carrying materials to the mouth; the five following pairs are larger, and terminated by small bifid claws, but do not extend beyond the margins of the shell; the terminal legs, which are ten in number, are transformed into thin lamellated plates serving for branchiæ. These king crabs sometimes attain the length of two feet. They inhabit the tropical seas, frequenting the coasts, and appearing to be found only in the East Indies and the shores of America. According to M. Leconte, they are given to pigs for food, and the long and pointed tail is sometimes employed by the Indians for the points of their arrows. Their eggs are eaten by the Chinese. Fossil

D

species are described and figured by Knorr in his *Monuments of the Deluge*. There are two genera, namely, *Tachyphlares*, having the four anterior legs terminated by a monodactyle claw in one sex; and *Limulus*, in which the two anterior legs in one sex are monodactyle.

LINEÆ. A small natural order of plants, separated from *Caryophyllææ* by M. Decandolle. It contains only two genera, viz. *Radiola* and *Linum*; there are only one species of the first, and above forty of the second, among which is the useful *Linum usitatissimum*, which yields that important article **FLAX**. The species are herbaceous or suffruticose plants, with simple entire leaves, usually alternate and without stipules, but sometimes with basal glands. The inflorescence is terminal, in racemose corymbs or panicles; the flowers are regular and united, either blue, white, or yellow, and very fugacious. The *Linums* are remarkable for the beauty of their flowers, but still more for, as has been already observed, the excellence of the fibre, which, when duly prepared, forms the flax of commerce, whence linen is made. Its seeds are oleaginous, and from them linseed-oil is expressed; and the residue after expression is the oil-cake upon which oxen are fattened. The seeds also contain a large quantity of bland mucilage, whence their use in decoction as demulcents; and linseed meal forms one of the best materials for cataplasms.

The flax used in this country is mostly of foreign growth, for notwithstanding the rewards held out by the legislature to encourage its domestic culture, it is found in well-peopled districts to be an unprofitable investment, not only for its inferior value to corn, but because it is such a scourge to the land on which it is grown. The *Radiola millegrana* is a small British annual found on sandy ground.

LINGULA (Lamarck), *Patella unguis* (Linnaeus). This singular mollusc is an instance of the vagaries exhibited by nature in her productions; and whenever they occur they give rise to infinite speculation in the minds of naturalists, to reconcile their apparent anomalies with the general laws that govern the structure of other creatures in the same branch of creation. Many of these sports of nature, or monstrosities, if we may presume so to term them, are to be accounted for by local or adventitious circumstances; but all we know of the greater number of them is that they are, and the why rests upon the most consistent train of philosophical reasoning that can be exercised in explanation; one constant conclusion we must always arrive at, that they are all peculiarly constructed for some wise purpose, and form so many additional proofs of infinite wisdom. Without enumerating any of the circumstantial details handed down to us by Aristotle, Pliny, and the early naturalists, respecting dragons, mermaids, and other fabulous creatures of that dark era of superstitious ignorance, or quoting instances of a far more recent date, when the good old Gerarde so solemnly affirmed that barnacles generated ducks and geese, we have only to ask ourselves what faith we should have placed in that person who first discovered or described a quadruped with its head to all appearance similar to that of a bird, as is the fact with the *Ornithorhynchus* or *Bradypus platypus*, had we not the evidence of our own senses to confirm it; or could we have credited that this planet was once tenanted with the stupendous race of creatures whose fossil remains are daily brought to light by the indefatigable zeal of geologists,

and whose existence goes well nigh to shake our faith even with their bones before us. It therefore becomes necessary for every one to pause and reflect, before he pronounces anything impossible in nature, or the dream of a poetic imagination, because he cannot readily fathom the anomalies it presents. Well may it be said that "travellers see strange sights," some of which, acting on an unenlightened mind, or but superficially observed, soon get clothed in fiction by frequent repetition, till at length they are worked up into a marvellous tale, too monstrous to be credited, though founded, in the first instance, upon one of those capricious examples of nature's power. We must not, however, dwell longer on a subject that would lead us into a wider field of speculation than it is our duty here to pursue, but return to the singular mollusc which has given rise to this digression. The *Lingula* is strictly a bivalve mollusc, its valves being of an equilateral, subequivalve form, truncated at their upper end, with a slight point in the centre of each, formed by the angular depressed rib which runs along the back of the valves, giving them the appearance of the upper mandibles of a duck's bill, whence the name of the species called, *Lingula anatina*; these valves are covered with a sea-green epidermis, and sometimes attain the size of three inches in length by half an inch in breadth, becoming much narrower or quite pointed opposite the patulous termination; but it is unlike every other bivalve, inasmuch as there is not the slightest indication of these valves being in any way connected together by the ordinary methods of nature. They possess no indications of teeth, hinge, or ligament; and their union would in vain have been guessed at, had it not been discovered that a junction is effected by means of the pointed ends of the valves being inserted, and vertically fixed in a fibro-gelatinous stem or peduncle, similar to that existing in the anatifa and its congeners. Linnaeus classed this mollusc with his genus *Patella*, and a more excusable error cannot be found in the annals of natural history, for had that great master seen no more than one valve of this shell, as some authors imagine, he could only conclude it to be a *patella* closely allied to those species which have since formed the genus *Parmophora*, to which the resemblance is rendered more strong by the valves of the *lingula* possessing small internal granular callosities, visible in the *Parmophora* and other genera of *Patella*; but it is equally obvious that had Linnaeus examined numberless specimens unconnected, or not *in situ*, he would still have found stronger grounds of confirmation in the conclusion he had drawn. Some naturalists have thrown out a hint that a connecting link might be traced between this mollusc and the family *Lepidacea*; but an examination of the anatomical structure of both leads to no such result, the fleshy stem being the only character common to each, if we except the long tentacular appendages existing on both sides of the animal's body, and serving as a bait, the organs of smell, or feelers, by means of which their food is discovered and seized, and which are spirally folded within the valves when the animal is in a state of repose, their position being distinctly marked on the internal surface of the valves. Like the *Lepidacea*, too, these molluscs are limited to the locomotion afforded by the contraction or expansion of their flexible peduncle; they cannot remove from place to place, but live and die on the spot which first gave life to their egg or germ. Whether they are found in congregated families, like the

Lepidacea, we know not, but every reason tends to point out that such must be the case; these are therefore the only important similar characteristics, while the distinctive ones are far more remarkable. The lingula also cannot be a carnivorous animal, not possessing the strong horny or ciliated processes that enable the *Lepidacea* to crush and, as it were, masticate their food. These shells are found in the Indian Ocean and Molucca Islands. Two species are mentioned, besides that described by Lamarck, but we only know of this one. De France describes two fossil genera. In the arrangement of De Blainville's *Malacology*, this genus is the first of the order *Palæobranchiata*, first section; and in Lamarck's system it is the first genus of the class *Conchifera*, first order *Monomyaria*, first tribe *Brachiopoda*, in which he includes the genera *Terebratula* and *Orbicula*.

LINNÆA (Gronovius). A genus named in honour of the celebrated Linnæus. It belongs to *Didymia angiospermia*, and natural order *Caprifoliaceæ*. Generic character:—calyx double; the exterior four-cleft; interior five-cleft; corolla bell-shaped; limb nearly equally five-lobed; stamens included; anthers ovate; style bearing a headed stigma; berry three-celled, two of them seedless; a creeping plant found on mountains in Scotland.

LINTHURIS (De Montfort). A microscopic fossil mollusc, described by De France as nearly allied to the *Nautilacea*.

LION. See CAT.

LIQUORICE is the *Glycyrrhiza glabra* of Tournefort, cultivated for the juice extractible from the root. See GLYCYRRHIZA.

LIRODENDRON (Linnæus). A genus of trees containing two species, which, from the amplitude of the flowers, are called tulip trees. They belong to *Magnoliaceæ*, are natives of North America, and have been long cultivated in Britain, forming a beautiful variety among other ornamental trees. They are commonly raised from seeds imported from America; and when sown in the spring, do not readily vegetate the first year, but lie inactive till the second year.

LISIANTHUS (Brown). A genus of trees, shrubs, and biennial herbs, natives of the West India islands. The flowers are pentandrous, and the genus belongs to *Gentianeæ*. Generic character:—calyx somewhat bell-shaped, five-cleft, margin of the segments colourless and lying back; corolla funnel-shaped, throat beardless, limb five-cleft; stamens inserted into the base of the tube; anthers arrow-shaped, two-celled; style elongated; stigma in two plates, or shells; seed vessel two-celled, dissepiments and valves, turned back. Some of the species are handsome flowering plants, and well worth cultivation; they are readily propagated by cuttings struck in sand under a glass.

LISSOCHILUS (R. Brown). A genus of splendid flowering *Orchideæ*, natives of the Cape of Good Hope. They grow best in turfy peat, mixed with a little loam; and can only be increased by divisions of the root.

LISTERA (R. Brown). A genus of two British plants, belonging to *Orchideæ*, formerly called *Neottia* by Richard, and are the "twayblade" of English botany, commonly found in damp woods.

LITHERINA (De Ferussac). A genus of molluscs separated from the genus *Turbo* of other authors. We do not, however, think the distinction sufficiently great to warrant its being constituted a genus.

LITHOLEPAS (Sowerby). A genus of molluscs possessing most of the characters common to the *Lepadiceæ*, and, like them, having its valves fixed to a flexible peduncle, at the base of which is a testaceous appendage resembling a reversed patella, consisting of eight contiguous pieces of an unequal size, six of them lateral, whose lower ones are very small, one large dorsal one, and one very small ventral one. The peculiar faculty this mollusc has of forming excavations in which it lives in the rocks of Mount Serrat, is unlike all other of its congeners; and the animal must be considered the type of an intermediate species between the *Lepas* and the *Balanus*.

LITHOSIIDÆ (Stephens). A family of nocturnal lepidopterous insects or moths, distinguished by the slenderness of the body, the length and narrowness of the wings, which are convoluted when at rest; the palpi are cylindric, and the antennæ are slender, and sometimes pectinated in the males. Latreille united these insects with many others into a family, which he named *Pseudo bombyceæ*, and they certainly very much recede from the typical appearance of the feathered full-bodied moths, having, in several respects, a much nearer relationship with the *Tineidæ*, with which also their larvæ nearly correspond. The moths do not present any remarkable peculiarities for notice. The genera are *Callimorpha*, containing the pink under-wing moth (*C. Jacobææ*), *Eulepia*, *Decopeia*, *Lithosia*, *Gnophria*, and *Setina*. The species of the last named genera, and especially those of *Lithosia*, are called footman-moths by collectors, from the colours, which are generally dull ochre or buff, with a narrow lighter coloured margin to the wings. The type of the genus is the *Phakæna noctua complana* (Linnæus), which has the anterior wings lead coloured, with the front margin clay coloured, and the posterior wings yellow. It is about an inch and a quarter in expanse, and is sufficiently common in woods near London. There are nine other species.

LITHOSPERMUM (Linnæus). A genus of annual, biennial, and perennial herbs, mostly natives of Europe. Several of them are natives of England, and the *L. officinale* is the gromwell of English botany.

LITUACEA (Lamarck, De Blainville). A family of molluscs whose animals are not at all known, without they resemble those of the *Spirula*. The genera included are mostly fossil; but the *Spirula* is a recent well known shell, and will more easily illustrate the characters of this family than a detailed description.

LIXUS (Fabricius). An extensive genus of coleopterous insects belonging to the family *Curculionidæ* or weevils, having the body long and narrow, and sometimes even linear, with the antennæ twelve-jointed, inserted behind the middle of the rostrum, the club being fusiform; the rostrum is long and cylindric, nearly straight, and not inclined to the breast; the femora are unarmed, and the tibiæ have a hook at the tip. The exotic species are numerous, but there are only five found in this country, the type being the *L. parapteticus*, the larva of which feeds on the stems of the phellandrium, and produces a disease in horses which may happen to eat it with the plant.

LIZARD (LACERTA, or rather LACERTIDÆ, the lizard family). The second family into which Cuvier divides his second order of reptiles, *Sauria*, and fol-

lowing immediately the crocodiles, which some of the larger species resemble a good deal in their appearance, though they are very different in their habits. Lizard has so frequently been used as the name of almost every saurian reptile, without exception, that the meaning of it is loose; and even the best systematic naturalists are hardly agreed as to the extent to which it ought to be applied; so that even Cuvier, whose judgment in the classification of animals according to the structure ranks so high, found it necessary to separate the family of lizards into two distinct orders—monitor lizards, and lizards properly so called; and we shall follow the same order in our brief notice.

Lizards are found chiefly in the warmer parts of the globe; and though many of them frequent marshy places, and the margins of the waters, and they are all to be considered as properly land animals, and not aquatic ones. Many of them can swim, and do take to the water; and some of the larger of these, which are of considerable size, though small in comparison with full grown crocodiles, prey upon small animals in shady places by the sides of the water, and occasionally upon fishes; yet they have not the strength nor the ferocity of the crocodiles.

The distinguishing characters of the lizards are:—the tongue slender, extensible, and forming two filaments or branches at the point; as in various kinds of serpents, they all move with rapidity, though in this respect there are considerable differences between them; they have five toes on each of their feet, three to their bases of unequal length, more especially on the hind feet, and all furnished with claws. Their bodies are lengthened; and their scales on the belly and tail are ranged in transverse bands. The tympanum is on the same level with the head, or only a little raised; a production of the skin, in which there is an opening, which acts as a sphincter, protects the eye by acting something in the manner of a third eyelid. The false ribs do not extend entirely round the body so as to form a complete circle. The opening of the ear is oval, and very conspicuous; but there is not an elevated crest either on the head or along the back. The tail is, at least, as long as the body. It is of a cylindrical form, and composed of jointed rings, and without upper crests. The feet are all nearly of equal length; and under each thigh there is a range of small porous scaly tubercles. There are five distinct toes on each foot, terminated by crooked claws. A good many of the species are found in woody situations, where they seek their food among the foliage, or in the underwood. This food consists chiefly of insects. Others inhabit ruinous buildings; and they are even met with near the habitations of man, subsisting partly on insects and partly on vegetables. A few others are found frequenting marshes, ponds, or lakes, where they prey on the small animals which inhabit them. The lizards are, generally speaking, active, lively reptiles, and, all circumstances considered, may be reckoned the least repulsive of all the saurian tribes. They are perfectly innocent in their manners; and not a few of them are of an agreeable form, and beautifully coloured, constituting pleasing objects in the scenery of tropical countries. This is especially the case with many of the smaller ones, which reside in dry places, and resort to the trees, among which their motions are often so rapid that they bear no inconsiderable resemblance to finely coloured birds.

Though the true lizards have not the ferocious disposition of the crocodiles, and few or none of them give out those poisonous, or otherwise offensive secretions which are given out by some other saurians, yet there are sometimes prejudices against them merely on account of their form, though others are highly esteemed in consequence of real or supposed services which they render to mankind by destroying animals more offensive than themselves. They are, as we have said, conveniently divided into two generic sections, monitors and proper lizards; and the first admit of sub-division.

MONITORS. This name is not very appropriate, because it is somewhat doubtful to what extent these animals give the warning against crocodiles and caymans which they are supposed to give; but they have been still more unfortunate in getting the name of a tribe of American Indians, the *Topinambos*, among whom an American species is called *Temnopora*; and Seba, we believe, in transferring this name into natural history, mistook the name of the people for the name of the animal; and accordingly, until Cuvier set them right, naturalists were in the habit of calling those large lizards *Topinambes*. They are by far the largest of the lizard family; and some of them grow to the length of five or six feet. They have teeth in both jaws, but none on the palate; and they swim better than most other lizards, in consequence of the tail being compressed laterally, and having a pretty strong lateral motion, so that it can act like the tail of a fish. They chiefly inhabit the edges of the waters; and very many of them find the principal part of their food by swimming; but there are also others which are, strictly speaking, land animals, and are found near the borders of the deserts. The cry which they utter when alarmed, or otherwise affected, is a sort of hissing whistle; and the reason of their being called monitors, or safe-guards, is supposed to be their uttering this cry on the appearance of the more formidable reptiles, and by that means warning other creatures of their danger; but the fact of their doing this is reported rather than proved.

Cuvier makes three sub-divisions of them:—monitors, properly so called, which are all inhabitants of the warmer parts of the eastern continent: dragons, which are found in South America; and safe-guards, which inhabit the same country. We shall notice one or two of the leading species in each of the sub-divisions.

MONITOR OF THE NILE (*L. Nilotica*). This is a species which has been much celebrated for the services rendered to mankind in protecting them from the crocodiles of the Nile, both by giving warning of their approach, and by eating the eggs and the young. How far this may have been true in former times cannot be very clearly ascertained; but in upper Egypt at least, it does not appear that much warning is given by this lizard, though it still continues to eat the eggs and the young of the crocodile. Crocodiles are not so numerous in the Lower Nile as they are represented to have once been, and they are not nearly so formidable, it being rare that any human being falls a victim to them. But in the south, above the cataracts, and about the province of Sennaar, where the climate is more tropical, they are far more formidable, and often seize those who are washing clothes, or otherwise employed near the edge of the water. This lizard grows to the length of five or six feet. It is of a brown colour, clouded with lighter or darker shades,

which form a number of variously shaped compartments ; and which shows how little dependence is to be placed upon the traditions of these animals which have been handed down from very early times. It is alleged that this lizard of the Nile is nothing but a crocodile which has been hatched in a place too dry for bringing the real crocodile to the maturity of its size and power. The teeth which are in both jaws are strong and conical ; but those in the back part of the mouth become rounded as the animal gets old. The tail is marked with regular rings of eye-shaped spots ; and though round at the base, it is marked with a keel for the greater part of its length. The ancient Egyptians appear to have been very partial to this lizard, for it is delineated on many of their monuments.

LAND MONITOR OF EGYPT. This species is termed *Ouaran el hard* by the Arabs, while the former is simply denominated ouaran. It is considerably smaller, though still a reptile of no inconsiderable size. The keel on its tail is also much less produced and fitted for swimming than that of the former, and its teeth are more compressed and have trenchant edges. This species is employed by the jugglers of Cairo in playing many tricks ; but they deprive it of its teeth before they venture to take many liberties with it. This species also has been known from remote antiquity.

THE MONITOR OF THE CONGO is nearly of the same size as that of the Nile, but it is more handsome in its colours. It is very abundant in the river after which it is named, and in several other rivers of Central Africa. It is ravenous in its feeding, destroying a number of offensive animals, and on this account the negroes entice it to their cottages, where it is a great favourite.

The species nearly allied to this one, but with trenchant teeth, and tails still better adapted for swimming, are very numerous in the rivers of Africa, of India, of the Oriental Islands, and of New Holland ; but they are so similar in their manners, that a detailed account of them would be little else than a list of different shades of colour. One of these from New Holland is blackish, variously clouded, and mottled on the back, and having the feet and the tail marked with rings of yellow. It is about three feet and a half in length when full grown, and it is said to attempt hiding itself in the water when it is pursued. There are few collections of animals in which specimens of lizards of this description are not found in considerable numbers ; but very often without any description or even the name of the place of which they are native, and thus they are of no use in illustrating the history of living nature. One of the most industrious explorers of these was Daudin ; but as he adopted the names of the American Indians, and the greater number of their species are not American at all, a slight air of ridicule is thrown over his otherwise meritorious labours.

The other monitors are distinguished by angular plates on the head, and large four-cornered scales on the body and tail, while the skin of the throat is covered with small scales, and marked by two or three transverse folds. There is a row of pores on the inside of each thigh.

THE DRAGON LIZARD is the type of the first of these sub-divisions. It has the scales elevated in the middle in the same manner as those of the crocodiles, and forming a crest on the tail, which organ is very

much compressed. But though it has more resemblance to a crocodile than any of the lizards have, it does not partake of the character of that animal ; and its habits are different, although the tail is compressed ; it does not swim rapidly ; but it runs well, and is very expert at climbing trees. It is found in the marshy parts of tropical America, where they are covered with trees. Some of the toes, especially those on the hind feet, are very long and slender : and the claws, though small, are firm and sharp pointed. It is not so aquatic in its habits as the other lizards of the same division ; and it spends much of its time in basking in the sun. It is rather a formidable reptile, measuring from four to six feet in length, and armed with powerful teeth, which, though it usually employs them only against those small animals upon which it feeds, it can yet turn into effective weapons of defence when an attack is made upon it. It is sought after with a good deal of eagerness, its flesh being not only eaten, but reckoned a great delicacy. Its swiftness and power of climbing trees render the catching of it no very easy matter ; and when it is surprised upon the ground, it generally contrives to escape into some burrow or crevice, where it bites very desperately in defence of its position. The numbers are not in proportion to the fertility of the animal, because its eggs are consumed by many of the frequenters of the same localities, and they are much sought after by the people, who prize them very highly, as being at once very delicate and very nutritious. The female produces several dozens of them in a season ; but, as is the habit with all the class, she pays no attention to them after she has once deposited them in ground fit for hatching them.

SAFEGUARD MONITORS. These differ from the species last described, in having the scales on the back and tail flat or without any keel. The teeth are notched in the young stage, but with age those in the hind part of the mouth become rounded. The more typical safeguards have the tail more or less compressed ; and they live on the banks of rivers, and can swim when occasion requires, though they spend the greater part of their time on the bank, and not in the water. It is this division which are more particularly said to give warning by their whistling sound at the approach of destroying reptiles ; but they themselves are destructive, though upon rather a smaller scale. They feed upon insects, of which they capture vast numbers, and also upon aquatic reptiles of inferior size, and upon eggs. Many of themselves, and also of their eggs, are in return eaten by the inhabitants ; and indeed, it is a remarkable property of the whole lizard family, that, with the exception perhaps of the green turtle, their eggs and flesh are more free from any rank or musky flavour than those of any other reptiles whatever ; while many of the animals upon which they feed, are such as it is desirable to get rid of.

THE GREAT AMERICAN SAFEGUARD is the most typical species. It is marked with yellow points and spots, disposed upon a white ground ; is blackish on the upper part of the body, and yellowish on the under part. It attains the length of six feet, though specimens so large are not very often met with. It runs with great swiftness along the ground, but takes to the water when hard pursued, where, however, it dives rather than swims ; and it keeps very near the bank for fear of the alligators. It burrows in the earth, where it digs its own hiding place. It is not under,

stood to be so prolific as some of the other species, but it is very generally distributed along the banks of the rivers and margins of places that are liable to be flooded. It is sought with nearly the same avidity as the species last mentioned. This sub-division is readily distinguished from all the other lizards by well marked characters. Thus the monitors of the old continent have the teeth sharp; and the true lizards of the same continent have teeth on the palate. From the iguanas again it is distinguished by the form of the tongue, which in them is neither extensible, nor divided into two filaments at the point as it is in every division of the lizard family. The iguanas were once ranked among the lizards by naturalists, and they are still called lizards in common language. It is the same with the crocodile family; but they are readily distinguished from the safeguard, though in nearly the same places and nearly the same size, by having only four toes in each of the hind feet, and having them more or less united by membranes, which is not the case in any of the lizards. There are other lizards bearing considerable resemblance to the safeguards, found in the same country, but distinguished by having the tail round and furnished with the same kind of square scales both on the body and on the tail. A slight notice of them was given in the article *AMEIVA*; but we may add, that though they have the general character of these lizards, yet they differ in some particulars. The country which these inhabit, is, however, so very extensive, that it has been examined by naturalists of discrimination at comparatively only a few points; and therefore it is impossible to discriminate the more minute distinctions of species, even though the subject were of sufficient importance, which, in a popular point of view at least, it is not. It seems, however, that as they get further removed from the water, and resemble more the common lizards of the eastern continent in their localities, they also resemble them more in their habits. Still, however, there is always a sufficient distinction to prevent a native of the one continent from being mistaken for a native of the other. Those American lizards, how similar soever they may be to the others in their external appearance, have no grinders, few of them have any colour on the throat, and the scales on that part of the body are very small. Some of these American ones are very handsome in their colours and quick in their motions; their average lengths are about a foot or eighteen inches.

THE LIZARDS, properly so called, form the second genus of the family; and as they are natives of the eastern continent, and many of them interesting, we shall give a brief enumeration of their general characters and the means by which they can be distinguished from those other saurians with which they have been so frequently confounded. The tongue differs little from that of the rest of the family; but the palate is furnished with two rows of teeth. A transverse band of broad scales forms a collar on the under part of the neck; while the part of the neck above and also the belly, or breast immediately below this collar, is covered with small scales. The body is lengthened, and never furnished with wings or flying membranes of any description. The feet have five toes on each, armed with claws, and grasping toward the centre, so as to take a firm hold of even a slight projection; but they are never so formed as to oppose each other in grasping. The bones of the upper part of the head project over the

orbits of the eyes and temples, so as to form a sort of canopy, which is either covered with large scales, or consists of one entire plate of scaly matter. The eyes are like those of the rest of the family; and under each thigh there is a row of little rough scaly projections containing pores. The scales on the belly are placed in transverse rows; and those on the back have slight keels; but they do not overlap each other so as to be imbricated like the tiles on a roof. The tail is composed of a great number of articulated joints; and it is round, and without any crest. This tail is exceedingly brittle, and a portion of it can be separated by almost the slightest touch; but it has the property of reproduction in a very short time. Lizards are monogamous, and always found in pairs; they are strictly land animals in their haunts, and never by any chance take to the water. They are found in most warm and dry countries, and in many parts of those which are temperate. In the latter they hibernate; and it is possible that in all countries they pass some considerable portion of the year in a dormant state. When excited by the heat of the sun they are exceedingly active, and have all the energies of life remarkably strong about them; but they can subsist for a very long time without any food. It is also probable that they live for many years; and indeed long life is a very general attribute of those animals which enjoy a seasonal repose in the course of the year. It is easy to see why this should be the case; for the awakening from this repose bears some resemblance to a regeneration of the animal into young life. Perhaps lizards are more susceptible to changes of the atmosphere than any other vertebrated animals; and therefore they may be taken as good indications of the characters of climates. They all live upon insects, and such small prey; and none of them possess any poisonous quality, or shows any disposition to attack a warm blooded animal, or, generally speaking, a reptile; but many of them when attacked defend themselves with great resolution, and bite much more keenly than one would be apt to suppose. It is indeed doubtful whether some of the larger species do not prey on the smaller, and also upon the more minute of the serpent tribes. They are abundant in some of the warmer parts of Europe. We shall notice one or two of the species.

THE GREAT GREEN LIZARD.—This is one of the most gaily-coloured of the whole family; and it is also the largest of all the true lizards. It occurs in all those parts of Europe which abut upon the Mediterranean, and have the climate and the soil warm. It is not found in the central parts of France, though it often is in the warm and sandy plains of Languedoc, where it pursues its trade of insect-catching with great assiduity during the summer months. The fact of its hibernating does not confine it so closely to tropical latitudes as many other animals which are less sensitive to cold; for it is met with in some places far to the north, or otherwise having the winter very severe. Linnæus enumerates it among the animals of Sweden, and Captain Cook found it in Kamtschatka, where the winter is exceedingly cold, though the summer both there and in Sweden is very hot. It is doubtful, however, whether there may not be several species confounded in the older descriptions; as spotted, streaked, and grey lizards have been sometimes confounded under the general

name of agile or nimble lizards, which is a property common to them all. It is rather a bold animal; and it is sometimes said to swallow mice and other small animals. When attacked it defends itself with great resolution; if its swiftness is not sufficient for enabling it to escape the danger, it will snap and bite readily at a stick; and when a dog attempts to seize it, it will bound upwards, and fasten on the nose of the dog during its descent. In many places it is supposed to be poisonous; and in not a few it is looked upon as endowed with supernatural powers of mischief. It is however perfectly innocent both as to the poison and to the league with the powers of darkness, and carries on all its operations by mechanical action, and in the light of the sun. The species and varieties (for the one is not clearly distinguished from the other) are however very many; and the manners of all are so much alike, that we must pass them over. There is, however, one of which some notice may be given, inasmuch as it occurs more abundantly in Europe than any of the others. This is

THE NIMBLE LIZARD. (*L. agilis* of Linnæus, *L. color* of Pallas, and the scaly lizard of Pennant.) This species is exceedingly numerous in France, Austria, and other parts of the Continent, in some of which its flesh is in much request as an article of food; and was once prescribed on account of supposed medicinal qualities, which of course it does not possess. It is so abundant in the neighbourhood of the Austrian capital, that Laurenti recommends it as food for the poor, and says "that during the season of its appearance, it would furnish by no means a scanty supply. It is usually termed the grey lizard of the walls, because it is seen very much upon dry walls in gardens during the summer months. In length it varies from five to six inches. The scales on the upper part are of small size and six-sided; the neck is nearly of the same thickness as the body; and the tail tapers to a point. This is a very lively and at the same time a most inoffensive animal, and there is something unpleasant in the account given of its domestic economy. The couple remain for a long time together, passing their winter in one sleep, and their summer in joint activity. The eggs are round, about a third of an inch in diameter; and though it is not understood that any incubation is practised by either parent, yet both are attentive to the young, seeking food for them, carrying them out to the sun when it is clear and warm, and removing them to shelter when it is dark and cold. These attentions are continued until the young have acquired sufficient strength to enable them to provide for themselves; and whenever this takes place, they are expelled from the paternal abode, and sent to seek habitations of their own. They have not long, however, to continue this operation during the first year of their lives; for the time of hibernating comes on soon after they come to maturity.

Such is a slight outline of the natural history, and a brief notice of some of the leading species of what may, perhaps, be regarded as the most interesting of all the families which compose the class of REPTILES.

LOASEÆ. A small natural order of plants, containing five genera and twelve species. *Loasa* and its typical allies are American herbs, with often scandent stems and tendrils, more or less covered with stiff hairs, and frequently furnished with stings. The leaves are opposite or alternate, without stipules, and simple, but often variously lobed and cut. The info-

rescence is axillary, terminal, or lateral; and the peduncles are flowered. The flowers are large and elegant, regular and united.

This order contains the following genera, viz.—*Bartonia*, *Blumenbachia*, *Loasa*, *Scyphanthus*, and *Mentzelia*.

LOBARIA (Müller). A genus of molluscs, not possessing the smallest rudiment of shell. This genus established by Müller, was previously called *Doridium* and *Bullidium* by Meckel, and *Acera* by Cuvier.

LOBELIA (Linnæus). A very extensive genus of beautiful herbs, natives of almost all parts of the world. Class and order *Pentandria Monogynia*, and natural order, to which the genus gives a title, viz.—*Lobeliaceæ*. Generic character:—calyx of five teeth; corolla tubular, irregular, cut lengthwise; limb two-lipped, the upper two, and the lower three-cleft; anthers united and bearded; style simple; a ciliated indusium under the stigma; capsule two-celled.

LOBELIACEÆ. A natural order of plants, containing the following genera, viz.—*Lobelia*, *Monopsis*, *Clintonia*, *Lechea*, *Lechea*, and *Cyphia*. Of these, there are ninety species, chiefly *Lobelia*, almost all fine flowering plants. Some of the species are medicinal; but some are dangerous if incautiously used. From the anthers of *Lobelia* being united in a cylinder round the style, like those of the class *Syngenesia*, Linnæus placed the genus in that class, in an order called *Monogamia*; but modern botanists refer it to his fifth class and natural order as above.

LOCUSTIDÆ (Leach). A family of orthopterous insects, belonging to the section *Saltatoria*, or those furnished with hind legs formed for leaping, and forming a portion of the great genus *Gryllus* of Linnæus, but distinguished by the shortness of the antennæ, which are filiform, prismatic, or ensiform: the males have the base of the wing covers (tegmina), not furnished with a circular spot of membranous texture, and the chirruping noise which they make is produced by rubbing the hind femora against the margins of the wing covers; the females are not furnished with an elongated exerted ovipositor; the wings and wing covers are not horizontal as in the crickets, but laterally deflexed like the roof of a house; the ocelli are distinct, and three in number; the upper lip is notched; the jaws are robust, horny, and dentated; the abdomen is conical and compressed at the sides. These insects are exceedingly active, leaping to great distances, and flying with equal agility, and at considerable heights, feeding voraciously upon vegetables, to which they are sometimes very destructive.

We have already alluded in our article *Gryllus* to the changes of nomenclature to which this and the other groups of the Linnæan genus have been subjected, and to which we conceive a more appropriate series of names cannot be adopted than those which we have employed, by which the too renowned locust of the Scriptures retains its generic name of *Locusta*. There are indeed many small British species congeneric with this celebrated insect, but they are of too diminutive a size when compared with their tropical brethren, to commit those devastations for which the real locust is distinguished. This species, the *Locusta migratoria* (*Gryllus migratorius*, Linnæus), and several others nearly allied to it, but of a still larger size are occasionally produced in immense swarms, and of which both as regards their migrations and the ravages which they produce, accounts are recorded in so many works of natural history and

voyages. Indeed, it may well be said, that of all our insect enemies, the locust is the most terrible, its countless myriads changing the appearance of a fertile country into an arid desert; reducing whole districts to the most frightful want, and of which even the death is a cause of misery from the immense number of bodies which, from their putrefaction, put a final stroke to the mischief by infecting the atmosphere with a poisonous effluvium, and thus destroying those which have escaped the horrors of famine. It may be said that our picture is too highly coloured; but these insects, and the effects which they have produced, have emerged from the domain of natural history, and become the materials of the history of nations, the different periods of their appearance being recorded in the narratives of the historian, like the sudden irruptions of hordes of barbarians, which are scarcely less to be feared than these winged plagues.

By the despiser of the small things of the creation, insects are alike regarded with disgust, or considered as unworthy of regard; we would, however, call to his remembrance, the fact, that out of the seven grievous plagues of Egypt, four were caused by frogs, lice, flies, and locusts. We are not amongst those who would teach natural history out of the Holy Scriptures, which were written for far higher ends, but we cannot avoid quoting from the account of the last of these plagues the following description:—"And the locusts went up over all the land of Egypt, and rested on all the coasts of Egypt, very grievous were they, before them were no such locusts as they, neither after them shall be such (i.e. as regards the vast extent of their devastations). For they covered the face of the whole earth, so that the land was darkened; and they did eat every herb of the land, and all the fruit of the trees which the hail had left, and there remained not any green thing on the trees, or in the herb of the field, through all the land of Egypt." Exodus, chap. x., vers. 14, 15. But it is in the second chapter of the Prophecies of Joel that we meet with the most splendid and poetical description of the ravages of these animals. Their coming is called "a day of darkness and gloominess, a day of clouds and of thick darkness;" evidently in allusion to their immense swarms hiding the sun during their flight:—"The land is as the garden of Eden before them, and behind them a desolate wilderness; yea, and nothing shall escape them."—"Like the noise of chariots on the tops of mountains shall they leap, like the noise of a flame of fire that devoureth the stubble, as a strong people set in battle array"—alluding to their great powers of leaping, and to the noise which they make in biting the plants with their strong horny jaws. "They shall run like mighty men, they shall climb the wall like men of war, and they shall march every one on his ways, and they shall not break their ranks;"—"they shall run upon the wall; they shall climb up upon the houses; they shall enter in at the windows like a thief." Thus accurately describing the fixed determination with which they pursue their migratory route, and which, as the writer is informed by a recent traveller in Syria and Egypt, is the mode of progression adopted by the larvæ and pupæ, which are destitute of wings, and which are so thick upon the ground, that at every footstep they are trodden to death.

This statement corresponds with that given with more minute detail by the Russian traveller Pallas, who tells us that in serene weather they are in

full motion in the morning, immediately after the evaporation of the dew, and if no dew has fallen, they appear as soon as the sun imparts the genial warmth. At first some are seen running about like messengers among the reposing swarms, which are lying partly compressed upon the ground at the side of small eminences, and partly attached to tall plants and shrubs. Shortly after the whole body begins to move forward in one direction, and with little deviation. They resemble a swarm of ants all taking the same course at small distances, but without touching each other; they uniformly travel towards a certain region as fast as a fly can run, and without leaping unless pursued; in which case, indeed, they disperse, but soon collect again and follow their former route. In this manner they advance from morning to evening without halting, frequently at the rate of a hundred fathoms and upwards in the course of a day. Although they prefer marching along high roads, footpaths, or open tracts, yet, when their progress is opposed by bushes, hedges, and ditches, they penetrate through them; their way can only be impeded by the waters of brooks or canals, as they are apparently terrified at every kind of moisture. Often, however, they endeavour to gain the opposite bank with the aid of overhanging boughs; and if the stalks of plants or shrubs be laid across the water, they pass in close columns over these temporary bridges, on which they even seem to rest and enjoy the refreshing coolness. Towards sunset the whole swarm gradually collect in parties and creep up the plants, or encamp on slight eminences. On cold, cloudy, or rainy days they do not travel. As soon as they acquire wings, they progressively disperse, but still fly about in large swarms.

On turning to profane authors we find equally abundant evidence that the locusts have lost none of their destructive powers. Pliny tells us that, in some of the countries of Greece, there existed a law compelling the inhabitants to destroy these insects in the three states, of egg, larva, and imago. And in the Isle of Lemnos, in particular, each citizen was bound annually to supply a fixed number of locusts. Entire legions of Roman soldiers were also employed for this purpose in the north of Africa, which country, as well as the western parts of Asia, has evidently been in all ages the most exposed to the attacks of these enemies of the human race. Oresius tells us that in the year 800 every vestige of vegetation disappeared from the face of the earth owing to the presence of the locusts, which being afterwards blown into the sea and their bodies washed on shore, emitted a stench as infectious as that arising from the remains of a mighty army, precisely as described by Joel, chap. xi., verse 20. And it is also said by St. Augustin, that a plague produced, or probably induced by the same cause, destroyed in the kingdom of Numidia and adjacent parts a population of 800,000 inhabitants.

But Spain, Italy, France, Turkey, Southern Russia, Poland, and even Sweden, have been at times visited by the destructive swarms of these insects, although our own island has been marvellously preserved; a straggling locust having, however, been from time to time found alive in this country, one of which is in the collection of the writer of this article, from that of Mr. Donovan. In the year 591, Italy was attacked by a terrible swarm, the effluvium from which destroyed, according to Mouffet, a prodigious number of men and beasts; and a famine was produced in

the kingdom of Venice, from which 30,000 persons perished. In 1600, Russia, Poland, and Lithuania were visited; the locusts arriving in such immense swarms that the air was darkened as in a storm. Wallachia, Moldavia, Transylvania, Hungary, and Poland, were invaded, in 1747 and 1748, by similar swarms, of which an account is inserted in the Philosophical Transactions. In 1749 they reached as far north as Sweden; and it is recorded that Charles XII. being in Bessarabia, thought himself overcome with a terrible tempest with hail, when a cloud of locusts fell upon his army, covering both man and horse, and impeding his march. During this visit their numbers were so great that they were compared to a fall of snow, or rather to a cloud of smoke passing rapidly along, and every spot where they stopped in their passage soon exhibited the most dismal desolation; the under herbs being first attacked, and then the leaves and even the bark of trees. In 1780 the kingdom of Morocco was subjected to the terrible ravages of these locusts, which produced a frightful famine, the poor being compelled to dig up and eat the roots of plants, and to hunt for grains of corn in the dung of animals, upon which they fed with voracity, the streets and roads being strewn with the dead bodies of the victims. In 1784 and 1797, Mr. Barrow, in his Travels in the South of Africa, has stated that they covered a surface of two thousand square miles; and when cast into the sea by a strong wind from the north-east, and washed upon the beach, they formed a line fifty miles long, and produced a barrier along the coast three or four feet high; and when the wind again changed, so powerful was the stench which their putrifying bodies caused, that it was perceived inland to a distance of 150 miles. Previous to the plague which devastated the Barbary States in 1799, the locusts covered the surface of the land from Mogadore to Tangier, according to Mr. Jackson, and presented a singular observation. The entire range bordering upon the desert of Sabara was ravaged by these insects, whilst on the other side of the river El Kos not a single one was to be seen. They had proceeded so far north, and then journeyed to the east, so that all the northern parts of El Araiche abounded in fruits and grain, whilst the adjacent country offered the most complete picture of desolation. They were at length swept into the Atlantic Ocean by a tempest, and, as at other times, a plague was produced by the odours exhaling from their putrifying bodies, but an abundant growth of plants followed their departure. The Arabs of the Desert, the enemies of their race, rejoice when the swarms of locusts arrive from the north, their arrival foretelling a general mortality, which they call *el khere*, or the blessing; they then quit their desert abodes, and, with a view of plunder, fix their tents in the districts attacked by the locusts.

The following circumstance, recorded in an American Journal, offers a convincing proof that the action of the wind is a great auxiliary in the migrations of the locusts. A vessel was detained in 1811 by a dead calm in the Atlantic Ocean, at a distance of about 200 miles from the Canary Islands, the nearest land; and a slight wind from the north-east having sprung up, the vessel was suddenly visited by a cloud of these insects which lighted upon the deck, rigging, &c., and, instead of appearing fatigued by their long flight, they sprang into the air on being attempted to be taken hold of by the sailors; the wind, which was but slight, continued for one hour; during which

time the locusts continued to fall upon the vessel; many also fell into the sea.

The propagative powers of locusts are so prodigious, that in the countries which they thus visit in swarms, in a very little time it is easy to collect their eggs by baskets full. In the south of France, where some species appear at certain seasons, and produce much detriment, sums are given for certain quantities of these eggs, and which are then destroyed. This was especially the case in 1613, 1803, 1822, and 1824, when fifty centimes (equal to 5d.) were paid for each kilogramme of eggs, and twenty-five centimes for each kilogramme of insects.

According to a statement made by M. Solier to the Entomological Society of France (Annales, vol. ii., p. 486), the city of Marseilles paid in the first mentioned year the immense sum of 20,000 francs*, and the city of Arles 25,000, for destroying the insects and gathering the eggs. In 1822, 1227 francs were paid; in 1824, 5542 francs; and in 1825, 6200 francs for this purpose; but in these latter years the number of locusts could not be compared with that of the year 1613, when they destroyed 1500 acres of corn in the environs of Arles. Their migrations in 1780 in Transylvania were equally expensive, fifteen hundred persons being employed in collecting the eggs, each of whom filled a sack; and yet in the following year their numbers were scarcely diminished, for millions of eggs were after the spring dug up and destroyed by the inhabitants, who were called upon to perform this labour.

We have already said that many distinct species of *Locustidæ* have obtained the name of locust, which may be regarded as a generic rather than a specific term; in like manner the term migratory locust is employed in a general sense, and is applicable only to those which, having multiplied in a prodigious manner, owing to favourable circumstances, and consumed the entire vegetation of the district where they were produced, make their way to other districts in search of food. Many species of locusts, on the contrary, appear only in a single spot, where they do not multiply with such rapidity, although the variations of heat and cold, drought or moisture, influence the propagation of these as well as the true migratory species. In the following year, when the weather is dry and hot, the eggs are hatched, and the young locusts, resembling their parents in form, but wanting wings, are produced. The eggs are deposited in cylindrical burrows, several inches long, near the surface of the ground; they are easily discovered, the aperture not being closed. They are found in uncultivated ground, and the nest is an inch and a half deep in the species found in the south of France. The tubes or burrows are formed of a layer of earth covered by gluten, their diameter being that of the abdomen of the females, their direction being generally horizontal. The number of eggs contained in each tube is about fifty or sixty, which are inclosed in a very thin and common envelope.

We have hitherto spoken of the locust only as a destructive enemy; nevertheless, in certain countries, the inhabitants, as though anxious to make amends for its injuries, employ it both as a food and as an article of commerce. In Arabia they are collected in great numbers, dried, and used as bread in seasons of scarcity. The reader will also remember, that the

* A franc is equal to tenpence English.

food of St. John in the wilderness consisted only of insects or their productions—being locusts and wild honey. The writer hereof has tasted locusts cured in the Levant, and found them rather sweet, but of an insipid taste. According to some travellers, they are roasted or fried on a hot fire, their legs and wings, and, as some say, also their entrails, being first removed. In many parts of Arabia they are strung in rows by the women and children, and sold. By some they are seasoned, and by others boiled; and really, when we remember the vegetable nature of their food, there must, be less real ground of objection to use them in this manner, than there is to eat shrimps, prawns, crayfish, &c., which feed upon the grossest impurities. Certain it is, many nations do eat locusts cooked in one way or another, and have thence obtained the name of *Acridophagi*. It is also true that travellers have differed in their opinion as to the taste of this kind of food. Some have also asserted that a continued use of it produces ill effects; but the observations upon this subject are too vague to allow us to be certain on this point.

In this country we possess about twenty-five native species belonging to the genus *Locusta*, of comparatively small size, and which are found on grassy banks and commons, &c.; about eight species of *Gomphocerius*, Leach (in which the antennæ are thickened at the tips), and several species of *Acrydium* (*Tetrix*, Latreille), in which the prothorax is produced into a long point behind, covering the remainder of the body. These last are the smallest species of the family. The exotic species are very numerous, and often very brilliantly coloured.

LOCUST TREE is the *Hymenæa courbaril* of Linneus, an ornamental West Indian tree, belonging to *Leguminosæ*.

LODDIGESIA (Bot. Mag.). An under-shrub from the Cape of Good Hope, named in honour of Conrad Loddiges, a celebrated nurseryman of Hackney. It belongs to *Leguminosæ*, is grown in loam and moor-earth, and increased by cuttings.

LOGWOOD is the *Hæmatoxylon Campechianum* of Linneus. It is used medicinally, and also as a dye stuff; for which latter purpose many thousand tons are annually imported into this country.

LOLIGO (*SEPIA* LOLIGO, Linneus). A molluscous animal, whose description will be found under the article *SEPIA*.

LOLIGOPSIS (Lamarck). A molluscous animal, whose description will be found under the article *SEPIA*.

LOLIUM (Linneus). A genus belonging to the *Gramineæ*, and one of our best cultivated grasses commonly known by the name of rye-grass. It is an early shooting plant, and is, therefore, chiefly used in laying down permanent meadow, or pastures. It is also sown among clover to improve the quality of the forage; and sown and made into hay by itself, is the most valuable of all forage for horses. The seed is a very considerable article in the seedsman's warehouse, vast quantities being purchased by farmers every year. The *L. temulentum* is a noxious plant, and deleterious among wheat.

LOMATIA (R. Brown). A genus of greenhouse plants, introduced from New South Wales, belonging to the fourth class of Linnean botany, and to the natural order *Proteaceæ*. The species succeed in moor-earth, with a mixture of loam, and are increased by cuttings.

LONGCHOCARPUS (Humboldt). A genus of South American trees, belonging to the class *Diadelphica*, and to the natural order *Leguminosæ*. These plants were called *Dalbergia* and *Robinia* by other authors. They are stove plants, thrive on sandy loam, and may be increased by cuttings in the usual way.

LONDON PRIDE is the *Saxifraga umbrosa* of Linneus, a well known plant, common in every cottage garden.

LONDON ROCKET is the *Siumbrum irio* of Linneus, common on every old wall.

LONGICORNES. A very extensive subsection of coleopterous insects, belonging to the section *Tetramera*, and distinguished by the great length of the antennæ, and the generally elongated form of the body and short head. By the latter characters it is at once distinguished from the rostrated *Rhyncophora*, and the more or less rounded *Cychica*. The subsection corresponds with the Linnean genera *Cerambyx*, *Necydalis*, and *Leptura*, which see, and more especially the first of these articles under its family name of *CERAMBYCIDE*.

LONGIPENNES.—The second of the four families into which Cuvier divides the web-footed birds, and including those which are most discursive over the waters. They are in fact the characteristic winged inhabitants of the high seas, and sailors meet with them at almost every point from the one pole to the other. The character from which they get their family name is the great length of their wings. Their feet also have the hind toe free of the web, or altogether wanting. Those of the former character are, generally speaking, good walkers, resort occasionally to the shores at other than their breeding times, and some of them proceed inland, though none of them reside permanently there. Those which have the second character do not in general walk so well, are less commonly seen on land, and many of them skim along the surface with level wings, and tip the water with the webs of their feet to assist them in their motion. The family includes the petrels, the puffins, the gulls, the skuas, the albatross, the terns, the noddies, and the storm petrels.

LONGIROSTRES. Cuvier's third family of *Echassiers* or stilt birds, which comprises a great number of those birds which frequent the margin of the waters. The whole of them have a strong family likeness; their bodies are similar in form, in the distribution of their colours, and also in their manners. Cuvier divides them into two great genera, snipes and avocets, of which notices will be found under their respective names. See also the article *BRAN*.

LONGICERA (Römer and Schultes). A genus of deciduous shrubs, natives of various parts of the globe. They belong to *Pentandria* and to the natural order *Caprifoliaceæ*. These plants were formerly associated with the honeysuckles (now called *Caprifolium*), but as they differ in the shape of their flowers and habit of growth, they have been separated.

LOPEZIA (Cavanelli). A genus of perennial and annual herbs, natives of Mexico. The flowers are monandrous, and belong to the natural order *Onagrarie*. These plants are very handsome when in flower, and are desirable for the green-house when fresh imported seeds can be obtained.

LOPHIREÆ. A natural order containing only one genus, and of that one species only, namely the

Lophira Africana of Banks, which is called in English catalogues, "the African scrubby oak," a native of Sierra Leone. It is a beautiful shrub, with terminal corymbs of white flowers, and a one-leaved permanent calyx. The leaves are long, entire, and leathery.

LOPHIUS—angler, called also fishing-frog, wide-mouth, gaper, sea-devil, and a vast variety of other names, —a genus of very singularly formed fishes belonging to Cuvier's third family of fishes with spinous fins, namely, those which have the pectoral fins with pedicles, or something in the form of feet. They are the most characteristic fishes of the family, and accordingly they are placed at the head of them in the Règne Animal. The characters of the genus are, the skeleton partly cartilaginous, and thus approximating to that of the sharks and rays, though the fishes differ from them in many other particulars. The pectoral fins are supported as if on two arms, sustained by two bones, which have some resemblance to the radial and cubital bones of an arm, but which are really the wrist of the fin, which in those fishes is much more produced than in any others. The ventrals are placed much in advance of the pectorals; the gill covers and gill arches are enveloped under the skin; and they have no other opening posteriorly but a hole of moderate size for each placed behind the pectoral fin. This structure of the breathing apparatus is also an approximation to the cartilaginous fishes; and in consequence of the smallness of the gill openings, they can live a long time out of the water. They are exceedingly voracious fishes, have very wide mouths, and large stomachs, with great digestive powers, but the intestinal canal is very short. Three genera, or sub-genera, of them are found in Cuvier's great work. The greater part of them are inhabitants of the warmer seas, but one species, at least, is by no means uncommon on the British shores, both in the northern and southern parts, in the latter of which especially it often grows to a large size.

LOPHIUS, properly so called, forms the first sub-genus; it is the characteristic one; and the one which is most common on the British shores, though there is another species, or at all events variety, in the European seas. The name *lophius*, which signifies a feather, or rather perhaps more strictly the shaft of a feather, is applied to these fishes in consequence of some very elongated detached rays, which are situated on the head. The head is of vast size in proportion to the rest of the body. It is very broad, but depressed, and armed with spines in many places, which give the fish a most singular appearance. The gape is very wide and far cleft; the jaws are armed with sharp-pointed teeth; and the under jaw is surrounded with a fringe, consisting of a number of detached beards or filaments. There are two distinct dorsal fins; and upon the head there are three curious rays, one behind the eyes, which may perhaps be considered as a ray of the dorsal fin, and other two more near the extremity of the upper jaw. These consist of spinous or bony rays formed internally of bone, flexible, but without any joints in their length, covered for the greater part with the common integuments, and plentifully furnished with nerves. The last and middle one terminates in slender points; but there is something peculiar in the termination of the first one, for it ends in a little forked penon, or flattened expansion of the most sparkling silvery lustre. The articulation of those two rays to the bone of the head is equally curious. The posterior one embraces like a

fork the ridge of the bone; and thus, though it has a very firm articulation, and a free motion backwards and forwards in the mesial plane, it has comparatively little motion, or in fact none in the cross direction. The anterior one is differently articulated; for it embraces a loop which is formed on the bone, as if the two were a staple, and the eye of a bolt placed within that staple, so as to have free motion in every direction. These bones, though flexible, and partaking of the cartilaginous texture of the rest of the skeleton, are remarkably strong and also elastic, and they are furnished with a great number of muscles, forming altogether a very fine specimen of animal mechanism. The bases of these curious spines are seated between two spinous ridges, close by the sides of which the eyes are situated, of large size, and directed upwards. The integuments covering the gills form two sacs of ample dimensions, which bring the head to a shape very much resembling that of a frog in the tadpole state; while the body seen from above, is so narrow in comparison with the head, that it is not unlike the tail of a tadpole; and the pectoral fins bear some distant resemblance to the young feet of the tadpole in their early stage, and before the tail has disappeared. From the vast size of the head, and capacity of the sacs containing the gills, the pectorals are thrown to a very considerable distance backward, so much behind the ventral fins indeed, that they have the appearance of hind feet, though they really answer to the fore feet of footed animals. Notwithstanding the length and strength of their wrist bones, these fins are not very efficient in swimming. Indeed, as we have often had occasion to remark, the fins of fishes, with the exception of the caudal fin, are useful in directing their motion rather than in producing it. The vast head and comparatively small caudal fin of these fishes, make them but very slow swimmers; but the peculiar form of the pectorals, and the very advanced position of the ventrals, make them very expert at ascending or descending. They thus command the depth of the water rather than a wide range in lateral extent; and though their principal habit is that of bottom fishes, they very frequently come to the surface.

We have already mentioned the circumstance which enables those fishes to live for a considerable time after they are out of the water. Their pectoral fins also enable them to crawl about with more expedition than could be expected on the part of a fish, if we did not attend to the very curious structure of these ones. Some of the species which inhabit other seas, especially the muddy inlets from which the water ebbs away, have the power of leaping about like frogs. They have attracted attention, at least in that species which is common in the European seas, from the earliest times; and the oldest naturalists call them indiscriminately by the names of frogs and fishes.

THE ANGLER (*L. piscatorius*) is the characteristic species. It is of a uniform brown colour on the upper part of the body, with the membranes of the upper fins of a deeper tint; and that of the tail still more so. The under part of the body, and the ventral and pectoral fins are of a white colour. The fish is very singular, and far from being attractive in its appearance; but it grows to a large size, and its manners render it an object of considerable interest. It is found in the seas, upon most of the shores of the British islands, and also in those of the east of Europe,

including the Mediterranean and the Baltic; and thus many opportunities of observing it occur.

It is exceedingly ravenous, and most indiscriminate in its feeding; and the passage from its mouth to its stomach is so short and wide, that if the large mouth is opened, the contents of the stomach may often be seen, and live fishes taken out of it. Its fishing habit is, however, the most curious part of its economy; and it appears to make use of the little silvery pennon upon the anterior spine of its head much in the same manner as an angler makes use of a painted minnow, or other spurious bait. It lies in the mud at the bottom, and stirs that up by the motion of its pectoral and ventral fins. Many of the flounders, and other ground fishes, resort to any spot where the mud is stirred, because the stirring of the mud brings up those animals on which they feed. The stirring by the angler has this effect, and it also conceals the fish itself, the colour of which, with the exception of the penon, is by no means conspicuous. This penon is played in all directions just above the surface of the stirred mud. The smaller fishes approach it, and attempt to seize it as a bait; but the angler, from the structure of its fins, springs up with great velocity, and speedily lodges the beguiled fish in its capacious maw. This is a singular habit, and has been often descanted on; but perhaps the cause of its being more a matter of wonder than many other habits of animals which have passed without admiration, and indeed almost without notice, is the fancied resemblance which it has to the art of catching fish as sometimes practised by man. This resemblance is only fancied, however, and not real, for nature furnishes the angler with its rod and bait, and also with the instinct which guides it in the use of them, without knowledge or contrivance of any kind upon its part.

The following quotations, as given by Mr. Yarrell, from the manuscripts of those accurate observers, Mr. Couch and the late Colonel Montagu, contain some of the most characteristic traits of this singular fish: "It makes but little difference," says Mr. Couch, "what the prey is, either in size or quality. A fisherman had hooked a cod-fish, and while drawing it up he felt a heavier weight attach itself to his line; this proved to be an angler of large size, which he compelled to quit its hold by a heavy blow on its head, leaving its prey still attached to the hook. In another instance, an angler seized a conger eel that had taken the hook; but after the latter had been engulfed in the enormous jaws, and perhaps stomach, it struggled through the gill aperture of the angler, and in this situation both were drawn up together. I have been told of its swallowing the large ball of cork employed as a buoy to a bulter, or deep sea line; and the fact this implies of its mounting to the surface is further confirmed by the evidence of sailors and fishermen, who have seen it floating and taken in with a line at midwater. These fishes sometimes abound, and a fisherman who informed me of the circumstance found seven of them at one time on the deck of a trawl boat; on expressing his surprise at the number, he was told that it was no uncommon thing to take a dozen at once."

"When this fish is taken in a net," says Montagu, "its captivity does not destroy its rapacious appetite, but it generally devours some of its fellow prisoners, which have been taken from the stomach alive, especially flounders. It is not so much sought after for its own flesh, as for the fish generally to be found in

its stomach: thus, though the fishermen reject the fish itself, they do not reject those that the fish has collected.

"A female examined measured three feet three inches; the breadth across the body, at the pectoral fins, fifteen inches; within the teeth, on the lower jaw, is a loose skin of a brown colour, like the back of the fish, forming a sort of bag, which probably assists in preventing the escape of its smaller prey. A male examined was three feet five inches long. When this fish was suspended by the head, the contents of its stomach were readily seen, and I perceived several cuttle-fish. The sexes are distinctly marked by external appendages, as in some species of *Raia*.

Another species of angler (*L. parvipennis*), is mentioned by Cuvier as being found, though much more rarely, on the coasts of France; and there is some probability at least of its having been seen in the Channel. It is of less size than the more common one, and has the second dorsal fin much lower; there is also a difference in the vertebra of the spine; the common species having thirty articulations, while this one has only twenty-five. Some other species have been enumerated by writers on the natural history of fishes; but they have been described from single specimens, which had been kept some time previously to their examination by the describers, and therefore but little dependence is to be placed on the accounts that are given of them.

CHIRONECTES forms the second subgenus of these singular fishes. Like the anglers properly so called, these have five rays on the head, of which the first is slender, and furnished with a sort of crest or penon at the top, while the others are margined by a membrane, which often extends partially from the one to the other, and gives this part of the organisation their form of a fin. In the whole genus, indeed, those rays on the head are of the same consistence as the rays of fins, and they are articulated in the same general part of the body, namely, on the dorsal line, as produced along the middle of the head. Whether entirely free or furnished with membranes, they are therefore to be considered as portions of the first dorsal. The body and head of those fishes are both very much compressed; their mouths open vertically; and the gills, which consist of four rays in each, have no external opening, except a small hole behind the pectorals. Their body is often studded with fleshy appendages. Their air-bladder is of large dimensions; their intestinal canal is of mere length, and not furnished with caecal appendages. Their stomach is of vast size; and many of them have the power of inflating it with air, as is done by the tetradons. On land their pectoral fins assist them in creeping, like a kind of feet; and they can perform this species of motion better than even the anglers. It is said that upon occasion they can live for two or three days out of their native element; and they very much frequent those floating banks of sea-weed which abound in the great eddies of the tropical oceans, nor are they found any where but in the tropical seas. They are much smaller than the common angler, the compression of their body is in the contrary direction, and their colours are more brilliant.

L. Hystrio. This is a species not exceeding nine inches in length, of a yellowish orange, and mottled with brown. It is found in the tropical parts of both oceans, generally near the sea-weed already alluded to; and the singular antics which it plays in leaping

out of the water and on the surface of the weed, have procured it the name of histrio, or the actor.

Another species, or perhaps only the last-mentioned one in a different age, has been noticed as occurring in the Indian Ocean, and an account of it was first given by Commerçon. It is of a nankin colour, marked with bluish brown spots, and the anterior filament or ray on the head is divided into three, and all round its mouth is thickly beset with soft thread-like appendages. It is sometimes kept in vases in the same manner as gold fishes; and at times it remains in a position as if it were entirely dead, after which it suddenly throws itself into the most playful attitudes. In the experiments which have been made with it while in a state of confinement, a change of its manners, from living in salt water to living in water fresh or nearly so, has been attempted, and we believe in part succeeded. There are still some other small species in the tropical seas, but their manners present nothing that can be very interesting to the general reader; and the published accounts of them in general confound all the species with each other.

MALTHÆ forms Cuvier's third subgenus. The fishes forming it have the head very broad and flat, especially where the sides are enlarged exteriorly by the sacs containing the gills. Their eyes are placed far in advance, and their mouth is of moderate size and protractile. Their gills contain six or seven rays, and open posteriorly by a hole below each pectoral fin. They have but a single dorsal fin, which is small and soft. Their bodies are roughened over with osseous tubercles, and there are filaments along the lines of the sides; but their heads are without the free rays which distinguish the true anglers. Among these may be enumerated the species which gets the name of the sea-bat, which is common in the warmer seas of America; and a few others which are met with also in the warmer seas, but they possess very little interest.

Although the genus *lophius* is one of the most singular of the inhabitants of the deep, and though it does not appear that the structure, or at all events the use of the structure, and more especially the habits of the angler of Europe, are very closely represented in any of the others; yet the tropical ones, being fishes not used as food, and therefore not generally taken by the sailors, belong to those margins of the revolving masses of sea-weed which grow in the water without being rooted, and in the whole history of which there is something very peculiar, though the internal parts of them are not very easily explored. Those great masses of floating sea-weed are found only in tropical seas, and only then in the broad waters, where the action of the tides and the position of the land tend to produce a circulating current. The weeds get into the eddy of this current, which, both in the South Atlantic and in the North, occupies a very considerable breadth; and as this weed is living, it has no tendency to approach the land. It affords shelter for countless numbers of small marine animals; and these, in their turn, feed a number of fishes. Radiated animals also abound in it, and some of the long-winged sea-birds resort to it as to a rich pasture. To traverse the thickest of this weed in a ship would be a heavy, and for anything we know, a hazardous task. It would be heavy, because of the mere interruption of the waters, and also because many, both of the plants and of the animals, would be apt to adhere to a ship's bottom and mul-

tily on it, to the great lessening of its progress through the water. It might be dangerous, for there are volcanic grounds in the neighbourhood of both accumulations, and there is no knowing how many discharges of volcanic matter may have been thrown up, and merely concealed by the surface. It is probable also that there may be coral formations in those very singular portions of the ocean.

LOPHOBANCHII. The fifth order of the fishes in Cuvier's arrangement, the characteristic of which is that the fibres of their gills are collected in little round tufts, which are arranged in pairs along the arches. This character is a very marked one, as there are no fishes but themselves which possess it. Their gills are covered externally in the integuments, so that there is only a small opening for the escape of the water. The surfaces of their bodies are covered over with a sort of armour consisting of angular plates of shelly matter. There are but few genera, *Syngnathus* and *Pegasus* comprise the whole. The first contains three divisions, sea-needles, sea-horses, and another species which has no very characteristic English name, though pipe-mouth is the nearest approximation. They are fishes of very singular forms, all inhabitants of the tropical seas, and none of them of any value in an economical point of view.

LOPHOTES. A genus of fishes belonging to Cuvier's eighth family of spinous-finned fishes, or those which have the body of a lengthened or riband-shaped form. They have the head short, surmounted by an elevated bony crest, to the top of which there is articulated a long spinous ray; and the rest having a membranous margin, and along the upper part of the back nearly to the tail there is a low fin with simple rays. The caudal fin is separate from the others, but very small, the pectorals are of moderate size, and the ventrals are so very small, as hardly to be perceptible. The teeth are pointed and a little serrated, and the mouth opens upwards. The eyes are very large; the only known species inhabits the Mediterranean, where it is very rare. It is in that sea chiefly that we find the most singularly formed fishes, and some of them not met with even in the same latitudes of the open Atlantic, or indeed nearer than the Indian seas; and it is worthy of remark too, that there are some shells still found in the Mediterranean, which are not now found except there and in the Indian seas; and that many of the fossil shells met with in those deposits, which have been evidently formed by the Mediterranean at some time or other, are also more connected with the Indian sea than with the Atlantic.

LOPHYRUS (Latreille). A genus of hymenopterous insects, belonging to the family of the sawflies (*Tenthredinida*), distinguished by the beautiful bipectinated antennæ of the males, forming a large triangular brush; those of the females are serrated. The larvæ have twenty-two legs, live in society, especially upon the species of the genus *Pinus*, to the young plants of which they are occasionally very injurious. There are three British species, the type being the *Tenthredo pinii* of Linnæus.

LORANTHÆ. A small but very curious natural order of plants containing two genera *Viscum* and *Loranthus*, to which has been added *Aucuba* by Bartling and Richard. This addition is, however, not yet fully sanctioned by other botanists, owing to the uncertainty respecting the character of the fruit of the *aucuba*. The *viscums* have little or no beauty, but the

loranthus is among the most lovely of plants, hanging in rich clusters of scarlet flowers from the branches of tropical trees which "they often clothe with beauty not their own." The mistletoe of the Druids is supposed to have been the *Loranthus Europæus*, the common viscum (mistletoe,) never being seen upon the oak, while the loranthus inhabits no other tree. "If this be so," says Lindley, "the latter must have once existed in this kingdom, although now extinct." It has been suggested that all vestiges of their religion were extirpated with the Druids, which will account for the loranthus having disappeared wherever that religion formerly held its sway. The mistletoe may be introduced into the bark of a hawthorn or apple tree, by merely sticking the seed upon a smooth part of the bark.

LORICERA (Latreille). A genus of coleopterous insects, belonging to the family *Carabida*, and sub-family *Harpalides*, distinguished by having the intermediate joints of the antennæ clothed with long hairs. There is only one British species, *L. pilicornis*, a pretty active species of a brassy green colour, found under stones.

LORIPEDA (Poli.) A genus of molluscs, so named by Poli, but now united to the genus *Lucina*, of which they appear properly a species.

LORY (*Loris*). A genus of four-handed mammalia, very remarkable for the slender form of their bodies, and their small and lengthened legs. The head is round, at the same time that the muzzle is elevated, and the nose produced to its extremity. The eyes are round, very large for the size of the animal, and placed so near to each other, that they are separated by only a thin partition of bone. The nostrils open toward the sides of a glandulous muzzle, down the centre of which there is a furrow, and there is a slight division of the upper lip; the ears are rounded; the tail is wanting, or so short as to be hardly visible externally, though there are six vertebrae in it. The limbs of the loris differ chiefly from those of the lemurs in their greater length and slenderness; they have all five toes, forming a true grasping hand, and having the thumb opposed to the rest, that on the hind foot being far removed from the others. The nails are flat, with the exception of that of the first toe on the hind foot, which is in the form of a crooked claw. The teeth bear a considerable resemblance to those of the galagos; the upper jaw has two small incisive teeth on each side, separated from the other two by a vacant space; there is also one canine and six cheek teeth; but the first three are only false grinders. In the lower jaw there are three long and pointed incisors on each side without a vacant space like that in the upper; and as is the case in the lemurs, the canines of the lower jaw lock inside that of the upper, contrary to the form in most animals.

In the loris, but we believe not in the lemurs, there is a remarkable formation of the principal arteries which supply the extremities with blood, that is, the subclavians and the femorals. Both divide into a ramified plexus of small vessels, which inosculate with each other, and form a sort of labyrinth, by means of which the current of blood to the limbs is greatly diminished. But though it is highly probable that this compound form of the vessel occasions a much slower circulation in the limbs of those animals than if that vessel was entire, yet the volume of the vessels is large in proportion to that of the limb, and it is

probable that the quantity of blood which it habitually contains is corresponding. It is certain that the motions of those animals are much more slow than those of any others with which we are acquainted, excepting perhaps the sloths, and their habit is altogether of a different character.

Though the loris agree in so many particulars with the lemurs, as have induced very many to give to the species which is figured in our plate along with the lemurs, the habits of the two genera are very different. They are both nocturnal, or, at all events, twilight animals in their feeding; but there is a remarkable contrast between the great vigour and rapid motions of the lemurs, and the feeble structure and creeping pace of the loris. The absence of a tail in the latter gives them an unfinished or mutilated appearance; and their slender limbs, long hands, and feeble joints, tend greatly to increase that appearance. The loris too are inhabitants of India and the Oriental Islands, while the lemurs are met with only in Madagascar; and it is worthy of remark, that the produced extremities and lengthened bodies of the loris give them some resemblance to the long-armed apes of the east. They are wholly climbing animals, reaching from twig to twig, whereas the lemurs are agile leapers. There are some very curious points in what may be called the physiological structure of the loris, chiefly in the female, which make them different from every other genus of mammalia; but the details of those peculiarities are interesting only to scientific naturalists, and even among them the use of this difference of structure has not been made out, so that in a popular point of view it is really of no use. There are two species at least which are known, and probably there are many others; for the forests which these animals inhabit are exceedingly close, and consequently difficult to be explored; and besides the nocturnal habits of the animals tend to make them less observed than if they were abroad on the branches during the day. The structure of their mouths is decidedly carnivorous; but still those which have been kept in confinement have not refused succulent vegetable matter. It is understood, that when in their native forests, their food consists chiefly of insects and small birds, upon which they are enabled to steal softly, and capture while reposing in the trees; because their motions are so slow and wary that they must occasion very little noise. Their large eyes indicate a strong power of sight, with only a twilight illumination; and the same extent of eyes renders them but ill able to bear the glare of the light, especially the strong light of a tropical sun. The closeness of the eyes to each other also indicates a forward motion toward an object which is in a state of repose; and this again forms a striking difference between them and the lemurs, which have the eyes at a considerable distance from each other, though not nearly so far apart as those animals which range for their prey, and course it by speed of foot. Indeed, to form a correct judgment of the difference in character between these two genera of animals, it is only necessary to examine the expression given to the two lemurs properly so called, and the lori or slow-paced lemur. We shall very briefly notice the two principal species.

THE SLOW LORI (*L. tardigrada*) is a native of India, and probably also of many of the eastern islands. It is of a greyish fawn colour, with a brown stripe down the back, and the space round the eyes

also darker than the rest of the body. During the day, and indeed at all times if it is fed in confinement, it is a slow and indolent animal, and seldom moves; and when it makes an effort at running either from danger or to its food, that effort is a very feeble one. It is by no means a vicious animal, and though it is not easy to stimulate its instincts, it does not appear to be so stupid as it is slow. It remains in concealment during the day, but as the evening closes it begins to move, grasping from branch to branch, and watching around it with apparent eagerness. It is said to prey upon the ground as well as among the branches; and when it spies a prize on a large branch, or on the ground, it creeps along perfectly motionless till within a short distance; then it elevates itself on the hind legs, advances a little quicker, seizes the prey between the fore ones, and speedily grasps it to death. Some which have been kept as curiosities have fed upon milk and ripe fruits, but they always preferred birds and the larger insects when these could be procured.

THE SLENDER LORI (*L. gracilis*). This is a much smaller animal than the former, and also more remarkable for the slenderness of its limbs. It possesses also some of the general characters which we have mentioned, though in greater perfection than the former one, such as the elevation of the point of the nose, and the projection of it beyond the upper lip; but we believe the two middle incisors are not so often undeveloped, or at all events wanting in the upper jaw, so as to occasion the vacant space to which allusion has been made. This species inhabits the island of Ceylon, and various other places in that neighbourhood; and the name is said to have been first given to it by the Dutch. Its general colour is brownish yellow on the upper part, and greyish on the under, with a reddish brown spot surrounding each eye, but without the dorsal line which characterises the other. Its size is rather less than the other species, being about that of a squirrel; its covering is remarkably soft, and it is altogether a very delicate animal. One which died a few years ago in the gardens of the Zoological Society measured between eight and nine inches in the body, five and a half in the hind extremities, and five in the fore ones, the difference being between the thigh bones and the bones of the arms.

The lorises are altogether singular creatures, and whether we judge of them by their structure or their habits, it is not very easy to assign, with accuracy, their place in the system of the mammalia. As we have said, their chief resemblance is to the lemurs; but then the lemurs themselves stand alone as a group. It does not appear that these creatures bear much analogy to any others which are found in the eastern islands, and especially in continental India; and therefore we must regard them as in a great measure forming one of those detached groups which we now and then meet with, more especially in countries having great peculiarities of climate; and of which we can neither assign the proper place, nor point out the structural advantages, until we have obtained an internal knowledge of all the peculiarities of the climates and their causes.

LOTUS (Linnaeus). An extensive genus of creeping herbs and under-shrubs, chiefly natives of Europe. Four or five species are found in Britain, where they are known as the bird's-foot trefoil. The flowers are papilionaceous, and belong to *Legumi-*

nosæ. The loti resemble the clovers in their general properties, but do not seem to be so acceptable as food to cattle. The pods of *L. edulis* are esteemed in Candia and Barbary, and those of *L. Gebelia* are eaten by the Arabs, being dressed when young as French beans are in Europe.

LOUREIRA (Cavanille.) A genus of evergreen Mexican shrubs belonging to *Euphorbiaceæ*. They are treated as greenhouse plants, grow freely in a mixture of loam and moor earth, and are increased by cuttings.

LOUSE. The generic English name given to several small species of apterous insects, belonging to the order *Anophura*, and family *Pediculidæ*, which are parasitic upon man and various animals, and distinguished by having the mouth composed of a short tubular proboscis or haustellum, by which they are separated from the bird-lice, *Nirmida*, which have the mouth mandibulated. Notwithstanding the disgusting nature of these insects, the writer on natural history ought not to be deterred from entering into a notice of their peculiarities, especially since, in several respects, they afford several interesting grounds of inquiry. Thus in respect to their situation in the systems of entomology, we find them a constant source of difficulty. They are entirely wingless, and the mouth in the species now under examination is rostrated, whilst in the bird-lice it is mandibulated; and yet the habits of the two groups are so identical, that this variation in the structure of the mouth (which in the true winged insects is considered as sufficient to warrant the establishment of the two classes *Mandibulata* and *Haustellata*) cannot be regarded as affording characters of a higher rank than those belonging to the family groups. Dr. Nitzsch, a celebrated German writer upon these insects, has, however, actually united them, from the structure of the mouth, with two distinct orders of winged insects, calling the former *Hemiptera-epizoica* and the latter *Orthoptera-epizoica*. Some authors again have regarded them as forming a distinct order of insects, which was named *Parasita*, whilst by others they were not deemed to belong to insects at all, but were placed with the *Centipedes* and spring-tailed insects, in a distinct class named *Ametabola*. Hence it is evident that the correct location of this group of insects demands an intimate acquaintance not only with this and all the other insect tribes, but also a just appreciation of the principles which regulate the distribution of the annulose sub-kingdom. Referring to our article *INSECT*, where we have somewhat concisely entered upon this subject, we pass to the account of the chief species of *Pediculidæ*. Of these the *Pediculus humanus*, or body louse, is of a whitish colour, and almost destitute of markings. This species is very abundant in various parts of Europe, although rare in this country. It frequents the garments and bodies of persons of dirty habits, being exceedingly abundant in the lowest classes in Poland and Russia, Portugal, and Spain. The species which is most abundant in this country is the *Pediculus cervicalis*, or head louse, which is marked on each side of the body by a dark line, and inhabits the heads of children and dirty persons, piercing the skin and sucking the blood. They are easily extracted by a fine tooth comb, or are destroyed by rubbing calomel mixed with bears' grease into the roots of the hair. Its eggs or nits are small pear-shaped bodies, termed nits, which are attached near the base of the hair by a glutinous substance. Swam-

merdam and Leeuwenhoek, two of the most celebrated of microscopic observers, have made the common louse the object of very elaborate investigation. The former tells us that notwithstanding the great powers of propagation of this insect, "it is no more than a jest that people say in sport that a louse may see its fourth generation in the space of twenty-four hours;" and Leeuwenhoek, who put a male and female louse under a stocking which he wore day and night to favour their breeding, found that the female lays from fifty to a hundred eggs, and, computing the natural increase from what he had seen, he says that in eight weeks one louse may see 5000 of its descendants. It is requisite that the eggs should be deposited in a place that is warm and moderately moist to produce any thing, and hence many nits laid on the hairs in the night-time are destroyed by the cold of the succeeding day, and so stick for several months till they lose their external form. In feeding, a constant motion of the intestines may be perceived through the transparent skin, the blood rushing like a torrent into the stomach. We have in our article on the Locust shown that from what is recorded of the immense swarms of these insects, their appearance, as one of the seven plagues of Egypt, may be supposed to have been produced without any supernatural effort of Providence: and indeed their arrival is not recorded in the Holy Bible as the result of a miracle, but in the plague of lice the contrary is expressly said, that, by the order of God, "Aaron stretched forth his hand with his rod, and smote the dust of the earth, and it became lice in man and beast; the magicians did so with their enchantments to bring forth lice, but they could not; then the magicians said to Pharaoh, this is the finger of God." This brings us to notice, without, however, venturing to speculate upon the precise species, or several species, or even tribes of parasites, of which the Egyptian plague consisted, that the term *Phthiriasis* has been given to a disease supposed to originate entirely in attacks of the *Pediculi*. Kirby and Spence have collected much information upon this subject, and conclude their observations by doubting whether there be any real *Phthiriasis*, and "that it does not appear from any well ascertained fact that the species of *Pediculi* are ever subcutaneous;" and that, therefore, the death of the poet Alcman and of Phrysydes Syrius, the philosopher, mentioned by Aristotle, must have been occasioned by some other kind of insect; for, when speaking of the lice to which he attributes these catastrophes, he says, that they are produced in the flesh in small pustule-like tumours, which have no pus, and from which, when punctured, they issue; but, according to the more recent observations of Alt, published in his *Dissertatio de Phthiriasis* at Bonn, in 1820, it appears that another species, *Pediculus tabescentium*, is the real louse of this disease, which, as cited by Bürmeister, collect in great numbers upon the skin at particular spots, chiefly upon the breast, the back, and the neck—between folds of the skin, making the surface uneven, so that scale-shaped lappets of the epidermis peel off, beneath which the lice conceal themselves. Of the first appearance of these insects much difficulty exists, both positive and negative evidence being recorded of their non-contagiousness. We cannot, however, adopt the opinion of Bürmeister, that they must necessarily be the result of equivocal generation; and by whom it is supposed that the skin, which has precisely the same structure as the mucous membranes of the in-

testinal canal, gives rise to parasites peculiar to it. The *Pediculus pubis* (or *Phthirus inguinalis*, Leach), is a fourth species; and, according to Fabricius, the louse of the negro is a fifth distinct species, of a black colour, with a large flat head.

The *Aphides* are also called plant lice; the *Nyctiribæ*, bat lice; the *Lepisma saccharina*, the sugar louse; and the *Oniscidæ*, wood lice.

LOVAGE. Is the *Ligusticum levisticum* of Linnæus, a large growing plant cultivated as a potherb. It partakes of the qualities of fennel, and is annually raised from seed.

LOVE APPLE. Is the *Lycopersicum esculentum* or tomato, of which there are three principal varieties, the white, red, and yellow fruited. These are all esteemed by Italian cooks and confectioners, and certainly make excellent sauces. The generic name is a bastard compound, signifying the wolfish peach, and like the English name, love apple, is meant to infer the deceitful character of the specious berries: in appearance they are more tempting than a peach, but as a fruit they are worthless.

LOVE LIES BLEEDING. Is the *Amarantus caudatus* of Linnæus, a tender annual border flower, seen in every garden.

LUCANIDÆ (Leach). A family of coleopterous insects, belonging to the section *Pentamera*, and to the subsection *Lamellicornes*, and comprising the various species of stag-beetles, or the Linnæan genus *Lucanus*, distinguished by the enormous size of the horny and toothed mandibles in the males, and by the rather long elbowed antennæ, which are terminated by a perfoliated club, and are composed of ten joints, the first being very long. The mandibles of the females are of small size, and hence the disparity in the appearance of the sexes is so great that it is only lately that the sexes of the great English stag-beetle have been discovered, Marsham having described the female as distinct. The lower jaws are slender and membranaceous, densely clothed with hair, and forming a kind of pencil, which are protruded by the insect for the purpose of lapping up flowing sap and other fluids, whereon the perfect insects feed. The mode in which the food of these insects is taken has been observed by Mr. G. R. Waterhouse, who communicated the following remarks to the Entomological Society. It appeared evident that their mandibles are employed in procuring subsistence, possibly by wounding the bark of young trees, in order to cause the sap to flow, upon which these insects feed. The male specimen of *L. cervus*, Mr. W. kept alive for several weeks, by feeding it with sugar and water; it also seemed fond of the juice of raspberries and other saccarine substances. For the purpose of lapping up juices or other fluid matter, it appears to have an extraordinary power of thrusting out the maxillæ, the terminal portion of which is extremely long and flexible, not unlike the tongue of a bee. It carefully avoided touching any thing with the antennæ, although these organs were kept continually in motion, as if for the purpose of feeling; if by chance they became smeared with sugar or any other matter, the insect immediately cleaned them by drawing them between the thigh of the fore leg and the underside of the thorax, in both which parts a velvet-like patch of hair is to be observed, which is well adapted for such purpose. That the mandibles were employed as above mentioned appeared evident, from the insect frequently biting the raspberry to wound it before it

applied the maxillæ; it also frequently attempted to bite Mr. Waterhouse's finger, without, however, causing a wound, and afterwards applied the maxillæ, but finding no fluid it renewed its attempts several times.—Ent. Soc. Trans., vol. I, p. vi.

The lower lip is in like manner formed of two shorter but similar pencils, and the mouth is closed beneath by a large horny plate, of a semicircular or square form.

The perfect insects are found upon the trunks of trees, such as the lime, the elm, and the willow; they sit with the head much elevated, in consequence of the size of the fore legs. They appear about the middle of summer, the males flying about in the evenings after sun-set. We have, however, seen *L. cernuus* on the wing in the middle of the day. The females are very sluggish, and seldom take wing. The larvæ of the common species, found in the rotten wood of oaks, willows, &c., are large fleshy grubs, nearly similar in form to those of the *Cetoniidæ*, and are supposed by some authors to have been eaten by the Romans, under the name of *Cossus*. In this state they live three or four years, at the end of which time they form a cocoon of chips of wood, glued together with a secretion which they emit, within which they are transformed to pupæ, and shortly afterwards to the imago state, when, notwithstanding the powerful and threatening aspect of the males, they are very harmless creatures.

The family comprises two sections, those with membranaceous and those with horny, toothed maxillæ, the latter comprising the exotic genus *Passalus*. The majority of the genera are exotic, and nothing is known of their habits. The three British species compose as many genera, namely, *Lucanus*, *Dorcas*, and *Platycerus*. The two latter are distinguished from the first by the comparatively smaller size of the mandibles of the males. The *Lucanus cervus* is the largest of our British beetles, and is common in some localities in the neighbourhood of London. The male is often two inches long, of a black colour, with chestnut-coloured elytra. It is subject to considerable variation in size as well as in the number of the teeth with which the mandibles are armed. The female is considerably smaller.

LUCERNE. Is the *Medicago sativa* of Linnæus, a valuable pasture and forage plant, extensively cultivated in some of the chalky districts of England and France. Whether as green food, or as hay for horses, it is inestimable.

LUCINA (Lamarck.) A genus of bivalve molluscs, whose animal is but little known, except the species mentioned by Poli—the Loricope. These shells seem allied to the telens, by the formation of their hinges, particularly on account of the lateral teeth. They also, in many of the species, possess an angular depression distinctly marked, but they are never sexuous. This circumstance probably induced Linnæus to class them with his genus *Venus*, which seems to have been a refuge for numberless stray bivalves now established into distinct genera. This shell is suborbicular, inequilateral, with small pointed apices. The hinge very variable in different species, but usually with two divergent primary teeth, one bifid—these change or become obsolete with age: two lateral teeth, the posterior one nearest the hinge, two muscular impressions very widely separated, the posterior one prolonged into a small band, sometimes extending to the centre of the valve. De Blainville

NAT. HIST.—VOL. III.

has included in this genus, this *Amphidesma* of Lamarck, and the genera *Fimbria* and *Corbula* of Cuvier, De France has described many fossil species.

LUCUMA (Jussieu.) A genus of South American fruit trees, belonging to the fifth class of sexual botany, and to the natural order *Sapotææ*. Generic character—calyx in five parts; corolla bell-shaped, swollen in the middle; limb five-cleft; stamens inserted into the tube; style simple; stigma obtuse; fruit an apple from five to ten-celled, each cell one-seeded. These plants thrive in rich loam, and may be propagated by cuttings.

LUNARIA (Linnæus.) A genus of biennial and perennial herbs, natives of Europe; so called from bearing broad silvery dissepiments resembling a full moon. The flowers are tetradynamous, and the genus belongs to *Cruciferaæ*. In English lists this plant is known by the name of "honesty."

LUNGWORT. Is the *Pulmonaria officinalis* of Linnæus, a British herbaceous plant found in damp woods. The leaves are speckled like human lungs.

LUPINUS (Tournesort). A genus of annual and perennial fine flowering herbs, mostly natives of America. The flowers are monadelphous, and the plants belong to *Leguminosæ*. The lupines need no description, being so well known. A few very fine perennial species have been introduced within these few years, which are among the gayest ornaments of the flower garden.

LUTRA—otter. A genus of carnivorous mammalia, belonging to Cuvier's second tribe, or those which are digitigrade, or walk on the toes; but which differ from the dog and cat families in the form of their bodies, which are long and flexible, and low on the legs, on which account they are sometimes called vermiform, or worm-shaped. This particular structure gives them great facilities in passing through small openings; and thus following prey which is not accessible to the other tribes of the order. In many particulars, the otter resembles the martens and pole-cats; but it differs in other respects. The characters of the teeth are: three false grinders in each side, both above and below; and a very strong talus or heel to the carnivorous tooth in the upper jaw. Their head is compressed, and their tongue is a little rough, or intermediate between that of the cat and the dog. But the chief particulars in which they differ from the martens and pole-cats, are those of the feet and the tail: the former being webbed and adapted for swimming, and the latter flattened horizontally. They are aquatic in their habits, and feed chiefly upon fishes, though they sometimes prey upon those smaller mammalia, which, like themselves, inhabit the banks of lakes and streams. They are all bold and strong animals in proportion to their size, their bite is very keen and determined, and they are resolute both in pursuit of their prey and in defending themselves when attacked. Though the teeth of the otters bear a very great resemblance, in number and in general structure, to those of the martens, yet the crowns of the cheek teeth are so formed as to be better adapted for bruising or grinding their food, than for cutting it. It must not be supposed, however, that this is decidedly an approximation to a less carnivorous habit than that of the martens; for though, from the form of their teeth, the otters could prepare vegetable food much better for their stomachs than the martens, the adaptation is chiefly to the nature of their finny prey, which, not being of so tough and fibrous a nature, is

E

more easily divided than the flesh of those warm-blooded animals upon which the martens and their congeners feed. The flattened tail possessed by the otters is common to all the four-footed mammalia which swim in the water, and pursue their prey there; and, unlike the tail of the cetacea, it is rather an organ of ascent and descent, than a propelling one, the forward motion being given chiefly by the stroke of the feet. We can trace a gradation in this respect as the animals are more and more aquatic; for the seals, which pass more of their time in the waters than the otters do, have the hind feet in great part united to the tail; and the cetacea, which are still more aquatic than the seals, have those extremities altogether merged in the tail. The otter's tail is covered with longer and coarser fur than the body; but there are, generally speaking, two kinds of fur, the one consisting of shining hairs which are longer and thicker than the rest, and generally of a brownish colour; and the other woolly, shorter, much thicker and finer, and generally greyish. The character of the fur appears, however, to vary a good deal with the climate. The otters of India, for instance, have the hair very rough; but in some cold countries, as for example in Kamtschatka, the covering of the otter is very soft and fine, and the skin is highly esteemed by the furriers. All the otters have the muzzle more or less developed; and mustachios in the greater number of the species, formed of a thick tuft of white or whitish hairs. The soles of the fore feet are quite naked; but in the hind ones the heel is covered with fur. The otter is not an amphibious animal, as is sometimes stated; for there are, in fact, no mammalia, and indeed no other animals, which are capable of breathing both air and water in the same stage of their existence; but the habits of the otter require that it should be much longer under water than most animals, and thus it requires to breathe less frequently. Otters of all species reside in burrows opening as near the water as possible, and very often concealed under a projecting bank. When they take to the water for the purpose of catching fish, they always swim against the stream; for the fishes, when reposing or waiting for food, always have their heads up the water; and thus the otter can come upon them unobserved, and make prize of them. It is often said that large pike and otters contend as to which of them shall eat the other; but though the pike is abundantly voracious, it is not so energetic, and does not bite so sharply as an otter. Otters are indifferent, in a great measure, both to cold and to moisture. Their fur has the property of the feathers of diving birds, in not becoming wetted; and as the greater part of their time is spent either in the water, or in cold and humid holes by the side of it, they do not know a very great change of temperature. They are thus found in countries which are comparatively cold; but it is understood that as the rivers freeze over, they retreat upon the unfrozen portion of the water; though when the frost is more than usually rapid and severe, they are sometimes frozen out; and this is the time when they are hunted with the greatest success, and also when their skins are the most valuable.

As there is much less difference of climate to an otter than to an animal which lives on the land, the coverings of the otters of all countries have more resemblance to each other than those of land animals. They are all greyish brown, more or less dark on

the upper part of the body, and they are generally white or whitish under the throat. For the reasons just mentioned, it is very difficult to find well marked distinctions of species in otters; and thus they who are fond of an excessive multiplication of species are obliged to call them after the countries in which they are found. We shall notice very briefly those species which are named.

THE EUROPEAN OTTER (*L. vulgaris*) is found in most countries of Europe, and it is the only species in this quarter of the world. Though short in the legs, it is a very long animal; the body of a full-grown one measuring two feet, and the tail nearly a foot and a half. Its general colour is blackish brown, with a white spot under the chin and a smaller one on each side of the nose. The nostrils are provided with an apparatus which prevents the water from entering when the animal is moving speedily along. This apparatus consists of a series of membranous valves, which are kept close by the pressure of the water; and that they may be so kept is another reason why the otter swims against the current. But though these appendages to the nostrils of the otter are a good temporary defence, they are only a temporary one; for if the otter is kept under water for any length of time, by being entangled in fishing nets or any other means, it is drowned with the same certainty as any other air-breathing animal, not by water getting into the lungs through the nostrils, but by strangulation from the want of the necessary stimulus of the atmosphere. The ears and eyes of the European otter are both very small, as a large size in either would be inconvenient; and we accordingly find that those mammalia which are still more aquatic in their habits than the otter, have the eyes smaller in proportion, and scarcely any external ears. But the eyes are the organs upon which such animals have their chief dependence in finding their prey under the surface. Ears are of but little use in letting what goes on under the surface be known to an animal which is also there; and nostrils, especially when closed by valves like those of the otter, are not more efficient. The small eye too is less liable to injury, or to be strained by the pressure of the water, than a large one would be; and the eyes of the otter are remarkably clean, and so placed as to be very commanding. The feet of the animal also answer well for their double purpose of swimming and burrowing in the earth. The feet of all animals which have the habit of diving under water, are short; and those of the otter, besides having this property, answer as mattocks with their fore claws, and as shovels, with spreading toes and strong ankles.

Their dwelling is sometimes in a natural cavity of the earth, but more frequently it is artificial, and with an opening at or under the surface of the water, a little below that part of the pool in which the fish usually lie. Though this dwelling of the otter is always in moist situations, the animal forms a regular nest of grass at the bottom of it, more especially against the breeding time. The period of gestation is about nine weeks, and the litter consists of four or five. The time when they make their appearance is generally about April, and the mother leaves them to shift for themselves in May. They are indeed not merely left to shift for themselves, but they are driven from the nest and its neighbourhood to find abodes and fishing grounds for themselves, but they remain in pairs, and attain maturity in the course of about two years. If taken

young, the otter may be tamed with less attention than many other animals, and it is curious that this is also the case with the seal, between which and the otter there are a good many points of resemblance. The food which they receive seems to have a considerable influence upon them; for if they are supplied with animal food, especially with their favourite food fish, at too early an age, they become sulky, disobedient, and even vicious; whereas, if they are suckled, which can easily be done along with puppies, or fed upon bread and milk, they are gentle and docile, and soon begin to show considerable attachment, and also some knowledge both of places and persons. It is a fact worthy of consideration, that the young, even of the fiercest carnivorous animals, are gentle and playful as long as they are fed entirely by the mother's milk; and if a portion of vegetable food is continued to them, their gentle disposition may be in so far confirmed into a habit. Even the cubs of lions and tigers, when very young, are as playful as kittens; and it is very probable that by continuing vegetable food to them, and breeding them again and again, with an increase of this food in every successive generation, they might in time be brought to show the same docility as other animals which are ferocious in the wild state, but gentle and obedient in the domestic. It seems, from this fact, which has been well ascertained in the case of many animals, that the effect of animal food is to stimulate the creature fed upon it to hunt and kill that which supplies it; but that this propensity may be diminished by a different kind of feeding. Of course this can operate within certain limits only; because the nature of the food cannot alter the form of the teeth of the animal, and the food must always be such as that these can prepare it for the stomach. The otter, as already said, has the cheek teeth much more nearly of a vegetable structure than those animals which eat warm blooded flesh, and therefore the softening of its disposition by means of vegetable food can be carried to a greater extent. It is the same with the seal, which, as it feeds chiefly upon fish, as well as the otter, naturally has teeth of a similar description.

Various individuals, fond of studying the dispositions and habits of animals, have tamed otters; and M. Frederick Cuvier had several of the common European ones, which were very familiar; and they were fed almost exclusively upon bread and milk. From their obedience, and their showing no disposition to be predatory, he very naturally concluded that the fact of their being trained to catch fish, and bring it to their master, which is mentioned by various naturalists, is by no means improbable. It is indeed strictly agreeable to the analogy which we find in the dog, in trained hawks, and in all other animals which are employed to catch prey. This training for hunting must, however, upon the principle above stated, tend to keep up a much greater portion of the natural ferocity of the animal than if it were merely domesticated, and kept on simpler food; but still the examples of other animals are so many, and so exactly in point, as to leave no doubt that both the otter and the seal might be trained to fishing, and employed with great advantage. Otters are more partial to wild and sequestered places than to the thickly inhabited and highly cultivated grounds, where the banks of rivers are generally cleared to the water's edge; but still they are very generally distributed over all those parts of the country which are fit for their distribution; and

they might easily be obtained anywhere in a domesticated state, if taken and trained where they breed, until domestication had produced such an effect on them, as that they would breed freely in that state. It must be understood, however, that it is domestication we are speaking of, and not mere confinement, for the latter always deteriorates the disposition of an animal, so that the most gentle dog imaginable may be altered to a snarler, if kept constantly on the chain for a sufficient length of time. In proportion as otters might be rendered valuable as fishers in the fresh waters, so might seals be rendered valuable in sea fishing; and as seals are found upon almost every part of the coast, much frequented by fish, there could be no difficulty in employing them. Indeed the seals themselves seem to give us a pretty broad hint as to the use that ought to be made of them; for tame ones are very apt to snatch up walking-sticks and other little matters belonging to their masters, and play about in the sea holding them up, as if to attract attention; but when this species of enticing failed in producing its effect, the seal would return with the stick, deliver it up after a little play, and then watch the first opportunity of seizing it again, in order to repeat the same trick. The seals to which we have alluded were, we believe, in great part fed upon bread and milk; and their extreme docility, and slight disposition to go a fishing on their own account, though very conveniently situated for it, being on a very small island, are very strong confirmations of what has been stated both of these animals and of the otter. Every one must be acquainted with the very amusing story of the "phoca," with which Monkbarns used so to torment the valourous Captain Macintyre, whom the phoca had rather ingloriously disarmed; and though there is perhaps no truth in the personal application, there is no question of the perfect accuracy as to the phoca itself.

We have mentioned these few particulars respecting the practicability of taming the otter and turning it to account, because the otter is a very hardy animal, very strong, and very bold and active both upon the land and in the water. It is an animal which could be employed in any climate or in any season; and as we have not such command over the stores of the water as we have over those of the land, every means by which this command, which is the command of articles the production of which costs us no trouble or expense, can be extended, are at all events deserving of a fair and complete trial. The same inducement has led us to add a few remarks on the seal, without which the notice of the otter would not be complete, as, generally speaking, the otter does not frequent the sea, though of course as it does not breathe water, salt water and fresh would be equally suitable to it.

But though the otter is thus susceptible of being tamed into a very harmless and tractable animal, it is very different in a state of nature, and the hunting of it is a matter of some danger as well as difficulty. It does not spring at the throats of men, or even of dogs, as is done by most of the carnivora which seek their food on land. Its mode of seizing its prey is by the part immediately behind the head on the back, and it retains its hold unless the piece to which it is attached is separated from the rest. This sometimes happens; and as wounds in the merely muscular parts are not fatal, and perhaps hardly painful, it is no very uncommon thing in rivers, where there are

many salmon and many otters, to find the former with otter-bites in the upper part of their backs. When an animal which catches prey by means of the bite has recourse to the same against an enemy, there is a similarity in the mode of applying it; and thus the method to which the otter resorts, when it is attacked, is to seize hold as firmly as it can, and retain that hold, but to lay hold simply of the part which is nearest to it. When taken by dogs, it is very apt to seize them by the fore legs, which are very sensitive, and retain its hold till the bone is broken; and in those parts of the country where the otter is looked upon as a formidable animal, it is said to do the same and persevere to the same extent in the case of human beings. It is further alleged, that experienced otter hunters put cinders in their boots, in order that the otter, in case of his seizing the boots, should be induced to mistake the crushing of a cinder for the breaking of a bone. That the otter, if hard pursued and in danger of its life, should bite the leg of a dog, or even that of a man, is highly probable; and when it does bite, it always bites very sharply; but that it should quit its hold upon hearing the snap of a broken bone, or any other sound, is so much at variance with the habits of the animal that it cannot be true. There seems to be as much truth in this as there is in the similar allegation, that the seal intentionally throws stones against those who pursue it on the shingly beaches; but there is certainly not any more.

There are some stories of alarm produced through fear of the otter, which, if they were in the hands of such a describer as Scott, might bear a comparison with the story of the phoca. We shall give the outlines of one:—A gentleman of the northern part of this island, equally eminent for learning, for humour, and for angling, but dashed a little with all with the prejudices respecting animals which reside by the highly picturesque streams of that part of the island, was one day threshing the water with his fly, and his zeal was rewarded by a trout of goodly size, which so excited him that he put it in his basket without depriving it of life. A friend and he had been a few minutes before talking of otters, of which some were known to inhabit the banks of the river in question, and the danger of their bite, and their proneness to give it, had been eloquently descanted on by the gentlemen in question. In the course of a few minutes his hook got fast in the herbage just by the margin of the water, and he lay down on the shelving and tangled bank in order to reach it: when he was fully stretched, the basket with the trout swung down a little, and the trout gave a violent wriggle. The axis of his body was nearly at an angle of forty-five degrees; and as his head was a little heavier than his heels, the heels rose in his effort to escape, and he fairly pitched a summerset into the river nearly chin deep in water, and with his face to the bank. The cause of this unexpected evolution and immersion, was a certain belief on his part, that the sound made by the wriggle of the trout proceeded from an otter whose strong hold he had invaded, and which was in the very act of fastening upon him in his defenceless position.

In times of abundance, especially when the salmon are ascending the rivers in high perfection, for the purpose of depositing their spawn, the otter is described as being dainty in its eating, and satisfying itself with the single piece which it can bite from the nape of the salmon, leaving the remainder of the

fish to its fate; and it is also said that the people residing on the banks are aware of the time that this is likely to take place, and knowing also that the otter is a connoisseur in his fish as well as his morsel, they watch his motions, and obtain an excellent supply from what he has left.

It has been already mentioned that salt or fresh water is indifferent to the otter as an element in which to perform its operations; and accordingly, though it prefers the fresh waters in those parts of the country where these abound with fish, and in the salmon rivers above all others, there are other situations in which even the European otter resorts to the sea, and practises its fishing along with, and much in the same manner as the seal. This occurs in the northern islands, and in various other places; and it generally takes place at those times of the year when the animal is driven from the inland rivers by severe frosts, or by scarcity of food.

When it is expelled from the waters by storms of frost or snow, it can alter its habit and become predatory upon the land; and when it does so, it can range to some distance, approaching farmyards, where it kills small or young animals, and to rabbit warrens, in which last it is very destructive, as it pursues the rabbits through the intricacies of their burrows with all the facility of a ferret. It is then that the capture of it affords the best sport, because there is a run upon the land, and the hunters always endeavour to get between it and the water, if there is any hole by which it can enter, or any pool left unfrozen. When it gains the unfrozen water, the capture of it becomes no easy matter; for having so much more command of itself than even the most expert water-dogs, and being apt to seize them and keep them below longer than they can bear, it is difficult to procure it in any other way than by shooting. The time for doing this is when it comes up to the surface to breathe, or to "vent," as it is technically called; but this requires quickness, as a small portion only appears above the water, and that but for a short time. Altogether, and without any regard to the mercantile value of its skin, which fetches a considerable price, the otter is an interesting animal, as being the only one of its kind found in Britain, or indeed in Europe. It is true that some continental ones have been mentioned more marked with white spots than otters usually are; but as the spots upon them are not constant, either in size or colour, those which are more spotted can be considered only as accidental varieties. The flesh of the otter is not eaten at the present time, at least in this country; but in Catholic times it was used on meagre days, and during Lent, and may be so still in some Catholic countries; for in the systematic arrangement of animals according to the canons of that church, the otter is a fish.

THE SEA OTTER (*L. marina*), is about three feet and a half long in the body; but the tail is much shorter in proportion than in any of the other otters, being about fifteen inches in length. The general colour is a beautiful maroon brown, though in some specimens it is clouded with other colours; and the head, the neck, and the under parts of the fore legs are brownish silver grey. The skin of this animal is accounted the finest of all furs, both in texture and durability, and on this account it is the most costly of the whole, a single skin often bringing in the markets of China and Japan, where furs are in great request, no less a price than twenty pounds. The Russians,

and also the English, send annually to these markets a great number of skins. The pile upon them is almost entirely of the woolly character, remarkably close and soft; its colour is very beautiful, and its lustre quite metallic and very durable. Such numbers of these valuable animals are found in the seas around Kamtschatka, that it is often called the Kamtschatka otter; but it is not confined to the shores of that country, or even to the shores of Asia; for it occurs equally on the west coast of the northern parts of America; but it has not been met with on either shore of the Atlantic, or any shore but in the North Pacific. As an inhabitant of the sea it makes a greater approach toward the seal in its structure than the common otter does. The principal indication of which is, that the hind legs are much shorter and brought nearer to each other, and the tail is also shorter; its toes are also shorter, and the claws shorter by the webs extending nearly to their points; and the hind feet resemble in no small degree in their terminal parts the feet of some of the diving ducks. The fore feet also are but ill adapted for walking; and the whole characters of the animal are much more aquatic than those of the common otter, or indeed of any other known species. It is often at least seventy pounds in weight; but we believe its flesh is of little or no value as an article of food. There are sometimes very considerable differences in the colour, the skin being slightly waved with lighter shades, and the head and fore paws almost white. During the winter months it confines itself to the shores of the sea, or to the margins of the ice, in those places where the water along shore is frozen; but during summer it ascends the rivers, and enters the fresh water lakes. It is a monogamous animal; and the male and female are usually found in company. The period of gestation is not very accurately known, but it is supposed to be not shorter than eight months; and there is not more than a single young one at a birth. Its food consists chiefly of fishes and crustacea, the coverings of the latter being readily broken by its powerful teeth. It is also said to eat the more succulent kinds of sea-weed, which is possible, inasmuch as the greater part, if not the whole, of the genus can eat vegetable matter. This one differs so much from the others in its habits, that it ought perhaps to be considered as a separate section of the genus, rather than as a mere species.

THE AMERICAN OTTER (*L. Americanus*) is very often styled the Brazilian otter, though that gives a false impression of it, because it is found in the rivers of North America as well as in those of South. It is doubtful, however, whether it extends as far to the north as otters are known to extend; for there is another species, or at all events a variety, in Canada, longer in the body, though not of larger diameter, than the species under notice; and there is also some difference in the formation of the tail, which indicates a more aquatic habit than that of the species under notice.

The American otter is rather larger than the European. Its covering is generally of a brownish fawn, colour a little bright on the upper part of the head, and darker towards the extremity of the legs and tail. The muzzle and the throat are of a whitish yellow. The colours are, however, subject to a good deal of variation, from dark yellowish brown to yellow on the upper part, and from yellow to nearly pure white on the throat. One distinction between it and the

European otter, is its having no distinct naked muzzle, but merely a margin of naked skin round the nostrils.

Its habits are described as being more social than most of the otters; for small troops are found inhabiting the same places of the rivers, and it is mentioned that several females take up their abode and produce their young in the same nest. The place of the nest is a natural hole in the bank, or a burrow excavated by the animals themselves. It appears to have a very considerable resemblance to the European otter in its disposition. In South America it has been domesticated, in which state it eats indiscriminately fish, the flesh of land animals, and farinaceous vegetables; but when it had a freedom of choice it always preferred fish to either of the others. It showed some attachment both to the house in which it was kept and to the inmates, for it would go out into the streets and come back again of its own accord; and if it met with any of the people of the house which were familiar to it, it would follow them much in the same manner as a dog. This following was, however, a very laborious matter, for its legs are so short that its belly nearly touches the ground, and thus it is obliged to leap instead of walking, and very soon gets fatigued. It showed a disposition to play with the other domestic animals, whose sport with each other consists, in great part, of good naturedly pretending to bite. This, however, was a sort of operation which the otter did not seem to understand, for when the dogs pretended to bite it, it always bit them severely in return. It showed no disposition, however, to attack and kill any warm-blooded animal, excepting on one or two occasions; and this was perhaps more by accident than from any disposition to make a meal of them. The account of this domesticated one is given by D'Azzara, and therefore it is probable that it may have related to

THE CHILI OTTER (*L. Chilensis*), which has been named and described as a species, though in reality it appears to be only a slight variety of the other. It is described as inhabiting the waters of Chili; being of a venous brown on the upper part, and yellowish or whitish on the under; measuring two feet four inches from the nose to the tail, with the tail one foot seven inches, and the circumference of the body nine inches and a half. We shall quote the more particular description of it from that given by Mr. Bennett before the Scientific Committee of the Zoological Society in January, 1832:—"The fur," says Mr. B., "is composed of hairs of two kinds; the inner woolly and thickly furnished; the outer silky, also thickly set, and completely concealing the inner. The colour of the fur of the upper surface is glossy brown on the head (where the hairs are comparatively short), and increasing in depth as it proceeds backwards, becomes blackish on the rump, and still more decidedly so on the tail. The lower surface of this member, for the extreme three-fourths of its length, is of the same colour with the upper; near the vent it becomes paler and assumes a reddish hue; and this colour is continued, with a slight cadescient tint, along the whole of the under surface, scarcely becoming lighter on the throat and lower jaw; the margin of the upper lip, the cheeks, and a patch under each ear, are of the same colour with the upper surface; of the mustachios, which are short, some of the hairs are yellowish, while greater part are bluish black; the legs are of the colour of the upper surface of the body, which becomes deeper on the feet; the whole of the silky

hairs exhibit that varying somewhat metallic gloss which is common to most aquatic mammalia."

Several other species or varieties of otters have been mentioned as occurring in one place or other of Central America; but most of them differ little from the more generally distributed species, except in size and colour; a mere list of them will therefore suffice.

The otter of Trinidad is about two feet three inches in length, and the tail measures a foot and a half. The upper part is bright brown, and the sides of the head, the throat, and the breast, whitish yellow; its fur is short and very smooth. It is probably nothing more than an immature specimen of the common American one.

The otter of Guyana is three feet and a half in length, and has the tail one-third as much. It is very bright brown on the upper part, with the throat and sides of the head nearly white.

The Carolina otter is rather larger than the preceding; blackish brown on the upper part, and with the sides of the head, extremity of the muzzle, and throat, greyish.

All the three, we believe, are described from mere museum specimens, which have no history farther than that they in all probability were brought from those parts of America after which they are named; and it does not appear that in structure or in habits they differ from that American variety whose history is better known; and indeed they differ so little in manners from the European otter, that any farther notice of them would be quite superfluous.

THE NIR-NAYKE OTTER (*L. Nair*), is a native of India, over which it appears to be pretty generally distributed; though in that wide country there may be expected to be varieties of colour similar to those of the American otters. It is about two feet and a half long, with the tail one foot and a half. There is less of the fine woolly fur upon it than upon the otters of colder climates. The upper part of it is bright chestnut, lighter on the sides of the body than on the sides of the back; the under part, the throat, sides of the head, and over the lips, reddish white; there are two spots of the same colour, one placed above and the other below the eye, of a russet colour, and the extremity of the muzzle is the same.

THE BARANG OTTER (*L. Barang*), is found in India, but more particularly in Java and the other isles to the south-east. It is sand brown on the upper part, has the throat brownish grey; the length of the body is twenty inches, and that of the tail eight. It is probable that this is an immature specimen of a larger species which is found in the same country, and which after all differs very little from that formerly mentioned.

THE CAPE OTTER (*L. inunguis*), is of course brought from Southern Africa. There are some distinguishing characters between it and the other otters, the most striking of which are found in the feet. The toes on the fore feet are thick and short, and joined by very short membranes, they are more unequal in length; the first phalanx on them is soldered to the next in the second and third; and there are no claws on any of the toes except on two large ones on the hind feet. It appears, however, to live by fishing indiscriminately upon fishes and crustacea. It is larger than the European species, but very closely resembles that one in the structure of its teeth. The general colour of the body is chestnut brown, and the throat and point of

the muzzle are white. It does not appear to differ much in its habits from the others, only the structure of the fore feet would lead one to suppose that it is incapable of digging a burrow for itself.

Such is a very brief outline of the otter genus; a genus, the species of which very much resemble each other, if we except the sea otter of the Northern Pacific. That one is unique, as it is the only one whose chief habit is marine; and it is peculiar in being confined to one locality, and also for the great beauty of its fur.

Altogether, the otters are very interesting to the student of natural history who wishes to investigate the adaptation of animals to the places in which they live. They are also remarkable for the very striking generic likeness which pervades them all, and not less for the variations of size and colour, which are almost the only distinctions that can be made between them, so as to form them into species. They are, therefore, exceedingly puzzling to those who place much reliance upon minute scientific arrangement; but they are not on this account the less inviting to the real student of natural history who can, with the exception of the sea one, find in the careful observation of any one of them, a very ample and very accurate representation of the whole.

LUTRARIA (Lamarck), *MYA* (Gmelin), *MACTRA*, of some authors. This mollusc was considered by Linnæus a *Mya*, and by more recent naturalists a *Macra*; it is, however, perfectly distinct from either, and is more nearly allied to the *Anatina*, to which it may be said to offer a natural transition to the *Mya*, preceding the *Macra*. This shell is inequilateral, transversely oblong, or rounded, gaping at the lateral extremities, hinge with one tooth, as it were folded or plaited in two, one side of which is plain, ligament internal and fixed in the hollow cavities of the primary teeth. The want of lateral teeth at once distinguishes these shells from the genus *Macra*.—See the following article.

LUTRICOLA (De Blainville). In this genus of molluscs De Blainville has included the genera *Ligula* of Leach, and *Lutraria* of Lamarck. The most of them inhabit the European seas, three only being described from the Indian Ocean. De France has described several fossil species. In the system of Malacology this genus thus belongs to the first section of the ninth family *Pyloridea*, third order *Lamelli-branchiata*, third class *Accephophora*.

LUZULA (De Candolle). A genus of uncultivated plants found on waste ground, in woods, or mountains, and belonging to the natural order *Juncææ*, of which it form a very interesting feature.

LYCENIDÆ (Leach). A family of diurnal lepidopterous insects, distinguished by the smaller size or rudimental structure of the fore legs, the entire and simple claws, the posterior tibiæ with a single pair of spurs. The larvæ are broad and resemble wood-lice, and the pupæ or chrysalides are attached by a layer of silk at the extremity, as well as by a cord passing round the centre of the body. This family comprises an extensive series of butterflies of small size, delicate structure, and comparatively feeble flight; by which latter character, as well as by the entire claws of the tarsi, they are well distinguished from the *Nymphalidæ*, amongst which the "swift Camilla" and the high-flying purple emperor pre-eminently exhibit the superior activity of the last-named family. From the *Papilionidæ* and *Hesperidæ* they are distinguished by

the more or less imperfect structure of the fore legs. Of these insects, the small copper and the little blue butterflies are amongst the most beautiful and the most common of our English species. The rich metallic copper of the former, and the intense silvery blue of the second, cannot fail to have attracted the attention of every observer of nature, and the very beautiful manner in which the undersides of the wings are pencilled with black spots surrounded by white eyelets renders a more minute examination of these insects equally pleasing. Some of the exotic species are more dazzling in their hues. There are about twenty-five British species, composing three genera, *Lycæna*, *Polyommatus*, and *Thecla*; known to collectors by the equally generic names of the "coppers," "blues," and "hair streaks," and which are distinguished in addition to their colouring by the following characters.

LYCÆNA, Fabricius (Coppers). Eyes naked, club of antennæ not compressed.

POLYOMMATUS, Latreille (Blues). Eyes generally naked, club of antennæ compressed.

THECLA, Fabricius (Hair Streaks). Eyes hairy, club of antennæ not compressed.

There are four British species of *Lycæna*, of which the *L. phléas* is the most abundant; the upper wings of a fiery-copper colour, with black spots, and varying in expansion from an inch to an inch and a half. It is found continually during the summer, there being several broods in the course of the season. The large copper, *L. dispar* (so named from the striking dissimilarity of the sexes), is found in the fens of Huntingdonshire and Cambridgeshire.

LYCHNIS (Linnaeus). A genus of annual, biennial, and perennial herbs, some of them bearing beautiful flowers, for which they are cultivated in the flower garden. They belong to *Decandria*, and to the natural order *Caryophyllææ*. They are all hardy except one, *L. grandiflora*, which is a native of China, and kept in the greenhouse or in a frame during winter. The cuckoo flower, *L. floscuuli*, of moist meadows, and the cockle, *L. githago*, of corn fields, are two well known English plants.

LICIUM (Linnaeus). Evergreen shrubs, and climbers, found in various parts of the world, both tropical and extra-tropical. The flowers are pentandrous, and the genus belongs to *Solanææ*. Those species which are natives of the south of Africa, are called the box thorn, and are almost hardy enough to stand in our well sheltered shrubberies, or against a wall. They thrive in loam and moor-earth, and are propagated by cuttings in the same kind of soil.

LYCOPERSICUM (Tournefort) is a South American genus, belonging to *Solanææ*. It is the love-apple of our gardens, and an annual raised from seeds in a frame, nursed in pots, and planted out against walls or pales in the summer, to yield fruit, of which fine sauces are made.

LYCOPSIS (Linnaeus). A genus of annual herbs, natives of Europe, and belonging to the natural order *Boraginææ*. In English lists, the *L. arvensis* is called wild bugloss, and was formerly known by the name of *Anchusa*, or *Nonæa arvensis*.

LYCOPUS (Linnaeus). A genus of aquatic weeds found in Europe; they belong to *Labiata*, and in English books the plant bears the name of water-horehound.

LYCOSA (Latreille). A genus of *Arachnida*, belonging to the division *Citigrades*, and distinguished

by the position of the eyes, which form an oblong square, the posterior not being raised on foot-stalks; the first pair of legs is longer than the second, but shorter than the fourth. These spiders are mostly found on the ground, where they run with the greatest agility, residing in burrows which they have formed, and the sides of which they line with silk. Some take up their abodes in crevices of walls, making silken tubes, which they conceal on the outside with bits of earth or sand. In these retreats they pass the winter, and undergo their moultings. They form their eggs into a mass covered with silk, and which they carry about with them, attaching it to the underside of their bodies, guarding it most sedulously, and exhibiting the greatest concern when it is taken from them. The young ones when hatched still hold themselves upon the body of the parent until they are of sufficient size to take care of themselves. The type of the genus is the common *Lycosa saccata*, the *Tarantula* also belongs to it. See **TARANTULA**.

LYCUS (Fabricius). A genus of coleopterous insects, belonging to the family *Lampyridæ*, but distinguished at once by the rostrated structure of the head. The species are very numerous, of singular form, and moderate size, being chiefly inhabitants of tropical climates. The very rare British species, *Lycus sanguineus*, is of the sub-genus *Dictyoptera* (Latreille), having the head very slightly rostrated. The species are found upon trees or flowers, and are generally of a red or yellow colour.

LYDA (Fabricius; PAMPHILIUS, Latreille). A curious genus of sawflies (*Tenthredinidæ*), distinguished by the multiarticulate structure of the antennæ (in which respect it approaches the *Siricidæ*), and by the broad depressed body and flat head. The species are of a moderately large size, handsomely coloured, and very rare in this country. The larvæ live in society under a silken tent upon various trees, especially the apple and pear; they are destitute in this state of the false or prolegs by which the larvæ of the sawflies are so well distinguished. The writer has observed a species which in this state forms its habitation in a spiral manner, like some of the caddice flies observed and figured by Reaumur.

LYGÆUS (Fabricius). A genus of hemipterous insects belonging to the family *Coccidæ*, having the antennæ four-jointed, slightly thickened at the tips, the ocelli are distinct, the head narrower than the prothorax, which is trapeziform. This is a handsome genus of field-bugs, the majority being gaily coloured and exotic. The *L. hyoscyami* is one of the handsomest insects of the family, of a scarlet colour with black spots, and is found upon plants.

LYME GRASS is the *Elymus arenarius* of English botany; a genus comprising many species found all over Europe, some of them useful as pasture plants.

LYMEXYLONIDÆ (Nob.; XYLOTROGI, Latreille). A very remarkable family of coleopterous insects, belonging to the section *Pentamera* and sub-section *Serricornes*, having the head not posteriorly lodged in the prothoracic cavity, the body long, narrow, and depressed, the maxillary palpi in the males having the second joint dilated and branched, forming a complete brush, the antennæ short, the tarsi entire, the four posterior long and slender. These insects are found in old trees; their motions are extremely active. In the exotic genus *Atractocerus* the elytra are extremely minute. The *Hylicætus dermestoides*

has been discovered this year (1886) in Sherwood Forest, on the 1st of May, on the trunks of old trees running very quickly, by Mr. P. Desvignes. The antennæ in this genus are compressed and serrated, but in the typical genus *Lymexylon* they are simple. Of this genus the best known species is *L. navale*, a single specimen of which has been taken in Windsor Forest by Mr. H. Griesbach. On the continent, however, this species is very abundant in the oak forests, and occasionally commits very great damage in the dook-yards of Sweden and France. The writer hereof possesses an undescribed species of this genus from New Holland, purchased from the collection of Mr. Haworth.

LYMNÆA (Linnæus, Cuvier). This well-known mollusc is abundantly found in our own rivers and ponds, particularly the latter, as it seems to prefer stagnant water to the running stream. It is not unfrequently two inches in length. The form of the shell is oval, turreted, or conical; substance thin, smooth, and the spire pointed, an ovate aperture extending widely from the front to the back; the edges disunited, the right side always sharp, the left with a very oblique plait or fold at the point of junction, between the columella and the remaining portion of the edge. The uniform characters of this genus

Lymnæa stagnalis.

render it difficult to distinguish the species, but fifteen or sixteen have been described as inhabiting Europe and America; two have been mentioned as natives of India: Africa and South America possess countless species, which remain unknown, from being too common to excite the attention of travellers—a circumstance constantly to be deplored in every branch of nature's productions; for were the same industry exercised in collecting the least attractive that now exists in obtaining the most beautiful, our knowledge of natural history would become immensely enriched, and many connecting links in the genera and species more satisfactorily accounted for. A naturalist, giving instructions to a young traveller in South America, requested he would collect for him every thing *ugly* in preference to the beautiful. This genus is so nearly allied to that of *Physa*, as to induce Sowerby to unite them; he does not think the latter being generally heterostrophe, or left-handed shells, of sufficient importance to warrant their division.

LYONIA (Nuttall). A genus of evergreen shrubs, separated from *Andromeda*, and discovered in North America by Nuttall. The flowers are decandrous, and the genus belongs to the *Ericææ*. The plants are proper for what are called American borders, that is, formed entirely of moor-earth. They are increased by seeds or layers.

LYPERANTHUS (R. Brown). A genus of tuberous rooted perennials, belonging to *Orchideææ*,

natives of New Holland. They are cultivated in pots of loam and moor-earth, and kept in a frame or greenhouse.

LYSIMACHIA (Linnæus). A genus of European herbs, belonging to *Pentandria*, and to the natural order *Primulacææ*. In Britain they are known by the name of loose strife; and a small creeping one, *L. nummularia*, found in most meadows, is called moneywort, from the appearance of its numerous golden-coloured flowers which enamel the turf. This plant is sometimes kept in pots as a window plant, and is as such very ornamental.

LYSYNEMA (R. Brown). A genus of evergreen ornamental shrubs, natives of Australia. Class and order *Pentandria Monogynia*, and natural order *Epacridææ*. Generic character:—calyx coloured and multibractate; corolla pitcher-shaped; segments of the limb beardless, turned or bent to the right; stamens below the germen; anthers horizontal; five scales round the germen; capsule with a columnar placenta. These plants thrive in coarse turfy moor-earth and sand, and are propagated by cuttings.

LYTHRARIÆ, or SALICARIÆ. A natural order of plants, containing in the last published books eleven genera, and above sixty species. Most of these are very showy plants, particularly the genera *Lythrum* and *Lagerstræmia*, which are the representatives of the order. They are chiefly natives of temperate climates, on mountains, and among bushes. The order is divided into two tribes; the first is *Salicariææ*, containing the genera *Peplis*, *Ammannia*, *Lythrum*, *Cuphea*, *Acisanthera*, *Lausonia*, *Heimia*, *Nesaea*, *Dacodon*, and *Grislea*; the second is *Lagerstræmiææ*, containing only the genus *Lagerstræmia*. *Lythrum* and its allies are herbaceous, rarely shrubby plants with tetragonal or subrotund branches, opposite, entire, glandless, and footstalkless leaves. The inflorescence is axillary, in cymes or spicate thyrsi; the calyx is persistent, with a bell-shaped tube, and cleft limb; the corolla is perigynous; stamens proceed from the tube of the calyx below the petals, and are variable in number; anthers are adnate, oval, and open lengthways; the ovarium is free, two or four-celled: style filiform; and stigma headed.

In the *Lagerstræmia*, the sepals are exactly valvate, the petals never absent, and the seed-coat expanded into a membranous wing, in which circumstance this tribe differs from the *Lythredææ*, whose seeds are wingless.

LYTHRUM (Linnæus). A genus of annual and perennial herbs, natives of Europe and America; class and order *Dodecandria Monogynia*, and natural order *Salicariææ*. The *L. salicaria*, or willow herb, is one of the most beautiful of our British native plants, frequent on the margins of brooks and rivers.

MACLEAYA (R. Brown). A genus containing one species, imported from China, belonging to *Papaveracææ*. It was formerly called *Boccornia* by Linnæus. It is a hardy plant, grows well in any light rich soil, and makes a fine appearance when covered with its large panicles of flowers; it is propagated by seeds or divisions of the root.

MACLURA (Nuttall). A genus of American trees, bearing monœcious flowers, and belonging to the natural order *Urticææ*. *M. aurantiaca*, from the shape and colour of its ripe fruit, is called the *Osage* orange. This is almost a hardy plant, and does pretty well if planted against a south wall. Two other

species have been added to this genus, viz. the *Morus tinctoria* of Linnæus, or *Broussonetia* of Heritier is *Maclura tinctoria*, and the tree which yields the fustic wood, used in dyeing yellow; and the *Morus Plumiera* of Burman is now the *Maclura Plumiera* of G. Don. The first was introduced into this country, with a view to its becoming a useful fruit tree; but it appears our summers are not warm enough to mature the fruit.

MACLURITA (Lesueur). This mollusc has been separated from the genus *Solarium* by Lesueur, without sufficient grounds, as it is in no essential point different, the principal distinction is the circumference of the umbilicus not being crenulated.

MACOMA. This mollusc was so named by Leach, but has since been united to the genus *Venus*, from which it so little differs as not to warrant a separation.

MACROCERA (Meigen). A genus of small dipterous insects, belonging to the family *Typulidae*, and sub-family *Fungivores* of Latreille, having the antennæ very long in the males, being sometimes much longer than the entire body. The ocelli are three in number, and form a triangle. There are several British species, all of which are rare.

MACRODACTYLES—Long toes. The last of the regular families into which Cuvier divides the stilt birds or waders. The habit of these birds is that of frequenting borders of marshes which are thick with tangled vegetation; and the toes of the bird are admirably fitted for enabling them to support their weight upon such footing. In some species these lengthened toes have scarcely any connecting membrane even at their bases; but in others they are lobed, or bordered with web, sometimes entire along the border, and sometimes contracted at the articulations of the toes. The bill is usually more or less contracted laterally, and long and slender, but without that softness and sensibility of touch which characterise the bills of the snipes. The coots and rails are British instances of those birds; and the *JACANA* (to which article we may refer for some remarks on the general habits), is perhaps the most characteristic of the whole.

MACRODITE. A microscopic mollusc, so called by De Montfort, now arranged under the genus *Lenticulina*.

MACROGLOSSA (Scopoli). A genus of lepidopterous insects belonging to the family of the hawkmoths, having the spiral tongue very long, the body robust, terminated by a fan-like tail, the wings not glossy, and the flight diurnal. The type is the humming-bird hawkmoth (*M. stellatarum*), of whose habits we have given a short notice in the article **HAWKMOOTH**.

MACROPODIA. A genus of triangular-shaped crabs. See **MAIIDE**.

MACRURA or **MACROURA**—Long tails. A sub-order of ten-legged crustaceous animals, having the eyes placed at the extremity of footstalks, and the abdomen elongated, equalling in size the remainder of the body, and not concealed, but simply bent under the breast, and terminated by a fan-like apparatus or swimmeret, having also on its under side five pairs of small appendages or false legs, with two filaments at the extremity of each. The abdomen is always seven-jointed, the antennæ generally long and exerted, the outer foot-jaws long, and not entirely covering the inner parts of the mouth. The shell is

longer and narrower than in the *Brachyura* or crabs, and generally terminated in front by a spine. These crustacea are marine, and do not quit the water like some of the land crabs.

The lobster, shrimp, prawn, &c., are examples of this sub-order, and which is divisible into five families, namely, 1. *Hippidae*; 2. *Paguridae*, or hermit crabs; 3. *Scyllaridae*, including the scaly lobsters, *Palinurus*; 4. *Astacidae*, or lobsters, and crayfish (see the article **CRAYFISH**), including the *Galathea* and *Porcellana*; 5. *Palaemonidae*, or shrimps. See the articles **CRUSTACEA**, **CRAB**, **CRAYFISH**, **ASTACIDÆ**, &c.

MACTRA (Linnæus, and modern authors). This mollusc, separated from the *Lutrariæ*, now constitutes a well-defined genus. They are marine shells, living in the sands, on the borders of the sea. Some species attain a large size; the substance is generally very thin, and covered with an epidermis. The form triangular, sometimes gaping a little backward, equi-valve, inequilateral, either smooth or transversely ribbed on the exterior, the summits protuberant and slightly bent forward. The character of the hinge is very singular, and clearly distinguishes this mollusc from all other bivalves; on each valve, beneath the apex, is a compressed tooth, bent or angular, like two divergent pieces, at the side of which is a subcardiform oblique cavity, to which the ligament is attached; there are also two lateral teeth, compressed and inserted, one of them more or less near to the cavity of the ligament, and the other near to the primary tooth. In some species, where the cavity of the hinge is very large, the primary tooth is oblique and almost obsolete, but the lateral teeth always exist; in addition to the internal ligament it possesses also an external one, which constitutes another distinguishing character from other bivalves; the interior of the valves presents two muscular impressions, united by a marginal ligula, narrow, and but slightly marked on the back part. About thirty-five species are described; they are found in the seas of every country, but the fossil species are by no means equally abundant.

MACTRINA. One of Captain Brown's fanciful genera, only to be found described in his comparative arrangement of the systems of Linnæus and Lamarck, upon a descending scale of the latter.

MACTROIDES. A division of molluscs well examined by some naturalists. To distinguish those of the confused genus *Venus*, whose characters resemble the *Maclura*, modern malacologists have now distributed them into more natural associations, the expediency of which is daily confirmed by the extended researches of naturalists, and the increased knowledge acquired by them.

MADDER. Is the *Rubia tinctoria* of Linnæus, an agricultural herbaceous plant, cultivated for the use of dyers. Madder is used as a dye-stuff, and also as a pigment. The madder-lakes, formed by precipitating the colouring matter from its infusion by alum, are, when carefully prepared, superior in tint to cochineal. Madder is not much grown in this country, although the climate suits it well enough, because it can be imported from abroad at a cheaper rate than it can be raised at home. Our chief supplies are received from Holland, France, Italy, and Turkey. It, like several other of the *Rubiaceæ*, tinges the secretions and excretions of animals that feed upon it. The urine and milk, and even the bones, become dyed red; and curious preparations are formed by feeding pigs alternately on madder and ordinary food, by

which means the constant deposition of osseous matter, and its constant removal, can be shown by the alternate layers of red and white in the bones, and the subsequent disappearance of all adventitious colour, when the use of madder as a food has been discontinued for a sufficient length of time. It may be proper to add, that the hardest part of the bones are coloured in a few days.

MADWORT. Is the *Alyssum saxatile* of Linnæus, a numerous genus of annual and perennial herbs and undershrubs natives of Europe. These herbs are, or were supposed to be, useful against the effects of the infection of canine madness.

MAGGOT. The name given to the footless larvæ of some species of insects. See the articles **GRUB** and **INSECT**.

MAGILUS (Lamarck). This most extraordinary mollusc, in its general appearance, might well be mistaken for a fossil substance, or petrified body. It is thick, ponderous, and resembling semi-transparent alabaster. The apex of this shell is turned round into a short oval spire, of about four whorls, resembling the form of the *Helix*; these, as the animal feels the necessity of extending its habitation, are filled completely with testaceous matter, assuming the appearance of a sculptured marble shell; the last whorl becomes prolonged by age in an irregularly undulating, but nearly straight direction, deserting its spiral turn; and, as additions are made to its length, the previous space occupied by the animal's body becomes successively filled. We have, however, upon one occasion observed several of these divisional portions merely separated from each other, without being rendered solid; this circumstance is of very rare occurrence. It is said that this tube sometimes extends several feet in length. This, by a parity of reasoning, may be possible; we have never witnessed examples even one foot long; and to all nature's productions in this or any other branch, a stage of perfection or completion of size is constantly observable, and seldom varies to any great extent; though the sports of nature are not unfrequent. The upper exterior part of this prolonged tube is convex, the lower side flattened, plaited, carinated, and somewhat angular, with closely set waved lamellar plates, much thicker on one side than the other; the interior rounded, smooth, and its lower side with a groove corresponding to the external keel. This mollusc is doubtless closely allied to the *Vermetus*, but yet nearer to the *Siliquaria*, from which it may be said only to differ by possessing a closed keel, instead of an open fissure. This shell, like the others mentioned, is not adherent, but merely enclosed in the madreporé which forms its habitation. The animal of this genus is quite unknown; but, like that of the *Siliquaria* and *Vermetus*, it is evident that it abandons the spiral portion of its shell in proportion as it increases in growth, augmenting the tubular portion, and filling up almost constantly the space previously occupied, while in its congeners a slight partition is only formed between the periods of distance, and forming as it were cells or chambers, which are never perforated as in the *Nautilaceæ*.

This mollusc is found imbedded in madreporé; we have only found it in the *M. sinuosa*, commonly called the brain madreporé; in this it is buried to a considerable depth according to the size of the madreporé, which sometimes is enormously large, as may be witnessed by a magnificent specimen in the

British Museum. In the early stage of the mollusc's development, no more than the few spiral whorls are imbedded, at which period a moderately long tube would reach the surface; but, in consequence of the growth of the madreporé being in a semi-spherical form, the animal of the *Magilus*, in order to keep pace with it, from a necessity of having an open communication to the exterior of its retreat, is forced to abandon its first intention of forming spiral whorls, which could never enable it to reach the surface, and by prolonging the last one attains its object, that of an exit at the nearest point. The waved lamellar parts distinctly indicate the periodical removals of the animal; but nothing is known of the age of this or other shells, from the impossibility of witnessing their birth and growth in any one instance. The *M. antiquus* is the only species known, and it is generally found in the madreporic formations of the Isle of France, and some parts of the Indian Ocean.

MAGNOLIACEÆ. A natural order containing five genera and thirty-seven species already described. The order is divided into two tribes, viz. *Illiciæ* and *Magnoliæ*. The first contains *Illicium* and *Drimys*, and the second comprises *Michelia*, *Magnolia*, and *Liriodendron*. The *Magnoliæ* and typical allies are splendid shrubs or trees, with simple alternate leaves, and convolute deciduous stipules, when young terminating the branches with a conical calyptra, like those of the fig, and when fallen leaving scars. The flowers are terminal or axillary; the flowers large, solitary, and often intensely fragrant—sometimes dangerously so. The sepals are deciduous, and nearly entire; petals from three to many; the stamens are indefinite and borne on a rim seated below the germen; the filaments are three, anthers long, two-celled, bursting longitudinally by clefts; the ovaries are many, in an imbricated series, each one-celled, one or more seeded, seeds sometimes suspended; the styles are short, and the stigmata simple.

The *Magnoliæ* are all highly ornamented. The hardy species from North America, and the more tender ones from Eastern Asia, are among the most interesting plants of our gardens. The *Illiciæ*, like the preceding, are aromatic bitters; as examples, the *Drimys Winteri*, the *Ternus moschata*, and the *Illicium anisatum*, may be mentioned. The former yields the true Winter's bark, which was found so beneficial & restorative to the crew of Captain Winter's ship, who accompanied the circumnavigator Drake.

MAHOGANY TREE. Is the *Suietenia mahogani* of Linnæus. East and West Indian timber trees, of which great quantities from Honduras are annually imported into Europe for the construction of household furniture. Young plants are kept in our stoves as a curiosity, and are raised by cuttings.

"The Honduras mahogany is less beautiful than the Jamaica wood; and it is not improbable that they are the produce of trees specifically distinct. About twenty thousand tons of mahogany are annually imported into this country: and a few years since Messrs. Broadwood gave the enormous sum of three thousand pounds for three logs of mahogany, all cut from the same tree. The duty on mahogany produces a revenue of nearly sixty thousand pounds per annum."—*Burnett*.

MAHONIA (Nuttall). A genus of shrubs nearly allied to *Berberis*, natives of North America, belonging to the sixth class of Linnæus, and to the natural order

Berberideæ. They have been but lately introduced into our collections, and, if hardy enough to bear our winters, will be considered a valuable addition.

MAIDEN PLUM. Is the *Comocladia integrifolia* of Linnæus, a genus of West Indian timber trees, belonging to *Terrbinataceæ*.

MAIDÆ (MAIADÆ, Leach; CRABES TRIANGULARES, Latreille; OXYRHINCHUS, M. Edwards). An extensive family of *Brachyura*, or short-tailed crabs, distinguished by the triangular or suboval form of the shell or carapax, attenuated in front into a sharp point, which is generally rough or spined; the eyes are lateral, the epistoma or space occupied between the antennæ and the cavity of the mouth is always of a square form; the claws of the fore-legs, especially in the males, large and long; the following legs are often very long, whence some of the species have obtained the name of spider-crabs; the two posterior legs are sometimes of a different form from the preceding. The number of segments in the abdomen is apparently variable, being often seven in both sexes, but in others the number is less, some of the joints (the intermediate) being soldered together. These crabs are inhabitants of the ocean, none having been observed in fresh water, nor upon the shores of the sea. All are found at great depths, and can only be obtained by means of dredging nets. Their motions, notwithstanding the length of their legs, are but slow, and they soon perish when taken out of the salt water. This family comprises the following tribes or subfamilies:—

1. *Macropodiens*; legs very long and slender; second and third pairs always much longer than the fore legs.
2. *Maïens*; legs of moderate size; second and third pairs not more than twice the length of the post-frontal portion of the carapax.
3. *Parthenopiens*; fore-legs much longer than the others.

This family comprises a great number of species, divided into many genera resting upon slight structural variations. The typical species is the *Maia squinado*, a large species found upon the southern coasts of Devon and Cornwall, where it is called the thorn-backed crab. Its shell or carapax is often to be seen stuck up in the fishmongers' shops of London as a rarity.

MALABAR LEAF. Is the *Cinnamomum Malabattrum* of G. Don. An East India tree, formerly the *Laurus Malabattrum* of Linnæus.

MALABAR NIGHTSHADE. Is a genus of cultivated plants in their native country, called *Bassella* by Linnæus. It belongs to *Chenopodeæ*, and is a climber.

MALABAR ROSE. Is the *Hibiscus rosa Malabarica* of Kirby, a fine flowering evergreen shrub, a native of India, belonging to *Malvaceæ*.

MALACHITE. This beautiful mineral is in reality a green carbonate of copper. It is found in various forms, but never regularly crystallised, the octohedral variety being a pseudo-crystal derived from the decomposition of another mineral. Malachite occurs in the greatest variety in the Uralian mountains; there are also some fine specimens in Cornwall, though it is but rarely found there.

MALACHIUS (Fabricius). A genus of small but handsome beetles belonging to the section *Pentamera*, sub-section *Serricornes*, and family *Melyridæ*, having the palpi filiform, the anterior angle of the

prothorax and the base of the abdomen furnished with a large vesicle capable of being retracted and dilated at will, and which the insect exposes on being alarmed, at the same time emitting a peculiar scent, which is evidently employed as a means of defence; the body is of an oblong and depressed form, and the males are distinguished by the irregularity of the joints of the antennæ, or by the extremity of each elytron being armed with a small spine or tubercle; this character is, however, found also in the females of some species. These insects are exceedingly active, and very voracious; they are found upon flowers, where they lie in wait for their prey, which consists of smaller insects. Two of the handsomest and commonest species are *M. æneus*, of a shining green colour, with the margins of the elytra broadly red (a quarter of an inch long), and *M. bipustulatus*, green with the tips of the elytra red (rather smaller than the preceding).

MALACHODENDRON (Cavanille). A North American shrub, forming a genus of one species, bearing handsome monadelphous flowers, and belonging to the natural order *Ternstroemiaceæ*. It has been long in our shrubberies, and known as the *Stuartia malachodendron*.

MALACHRA (Linnæus). A genus of tropical plants, mostly annuals, belonging to the class and order *Monadelphica Polyanthia*, and to the natural order *Malvaceæ*. They grow freely in any light soil, and are increased by seeds.

MALACODERMA (Latreille). A division of coleopterous insects, belonging to the section *Pentamera*, and sub-section *Serricornes*, having the body of a soft consistence, with the elytra flexible, the head immersed in the prothoracic cavity as far as the eyes, the prosternum not advanced into a point behind nor into a flattened plate beneath the mouth. This is a group of beetles of very considerable extent, the species being generally of a moderate size, gaily coloured, and for the most part frequenting flowers. It consists of the following families—*Cebrioidæ*, *Lampyridæ*, *Telephoridæ*, *Melyridæ*, *Cleridæ*, *Ptinidæ*, and *Lymexyloidæ*.

MALACOLOGY. This term is now adopted universally by naturalists, and to our thinking very properly, as applied to the study and scientific arrangement of that portion of creation called *Mollusca*, or molluscs; it includes a description of all the molluscous animals, either marine or terrestrial, whose bodies are commonly called *naked*, possessing merely elementary portions of testaceous matter, internally or externally situated, a partial shield or calcareous protection to some vital organ, or a well defined completely formed shell, serving as a protecting retreat to its architect under circumstances of necessity or convenience. The name is compounded of three Greek words—*μαλακος*, *ζωον*, and *λογος*. This, strictly speaking, should be rendered Malacozoology; but a constantly used idiomatic contraction in the Greek tongue sanctions its being shortened to a more convenient length. Malacology therefore means a treatise or discourse on *soft animals*. It includes all the *invertibrated animals*, which have their muscular system supported by external hard parts, and do not possess an internal skeleton, or any *articulated* portions, corresponding with the *Exanguia* of old authors, a division perfectly in unison with the white-blooded animals of Linnæus; not that it was imagined these creatures possessed no blood, but in contradistinction

to those circulating red blood. In olden times these singular animals appear to have been but little known, and Aristotle, the father of naturalists, gives the name of mollusc to such only as were naked, and that of *Ostracodermes* to those clothed with a testaceous covering; the first he defines as creatures without blood, whose fleshy parts are external, and the solid portions internal, the converse for all the others.

Linneus, adopting the same view, gives, with his admirable perspicuity, the following definition: *MOLLUSCA; A. simplicia, nuda absque testâ, artubus instructa: TESTACEA; A. simplicia domo sæpius calcario obiecta*. He and his disciples, merely attending to the characters of external configuration, lost sight of the natural affinities of these animals—affinities highly important to connect the chain of evidence in forming a system, and which can only be traced by a minute examination of the structure and functions of all the combined organs; a want of this care, for it can hardly be attributed to ignorance in that great man, has led to numberless errors and false conclusions; in the same genus animals were named respiring air, associated with others which perform the same function by means of gills in water; animals whose gills are like laminae, or leaves placed *externally*, with those having their gills situated in an *internal* cavity. And with regard to his classification of shells, independent of their inhabitants, many anomalies exist that should not have escaped the generally accurate judgment of such a naturalist, but proving the little attention he paid to this portion of nature. Notwithstanding these errors (and what system can be free from them?)—notwithstanding the necessity of the present classification from the increased knowledge we have acquired, the Linnæan system will always remain a key-stone in the circle of natural history.

Fabius, Columna, Lister, Willis, Swammerdam, and others, vainly published anatomical descriptions of *Mollusca*, with a view to establish a systematic arrangement of them in combination with their shells; no one possessed courage to carry on the scheme they suggested. Linneus does indeed mention, in the first editions of his *Systema Naturæ*, the animal before a description of the shell; but he confined himself to naming that with which the shell appeared to have the greatest connexion, and his genera of conchology are merely formed on the external configuration of the shell alone; in this he was followed by the greater portion of naturalists of the last century. *Mollusca*, as they are now viewed, may in general terms be thus described:—animals whose bodies and appendages of vitality are soft, and not articulated; they are enveloped in a muscular covering or skin, called the *mantle*, the form of which is extremely various in the different genera and species, and within or upon which exists what is called the shell, either univalve or consisting of one piece, bivalve or consisting of two pieces, or multivalve and consisting of more than two pieces, some without any rudiment of shell. These animals possess a perfect circulation of white or rather bluish blood, an aortic heart, with arterial and venous vessels, within which the blood circulates; they respire by branchiæ; the brain is a distinct mass, from which the nerves and *medulla oblongata* proceed; and there are ganglions in different parts of the body, that of locomotion being lateral; the senses vary; some of these animals possess distinct organs of sight and hearing, while others appear to be confined to the senses of

touch and taste. They are for the most part very low in the scale of creation; but the *Sepia*, or cuttle fish, presents an extremely perfect organisation, since it enjoys all the animal faculties of seeing and hearing well, and moving from one spot to another with ease and rapidity, and of being consequently able to pursue and seize its prey with the utmost facility; others, on the contrary, live and die on the spot which gave them birth, and depend, during the span of their existence, entirely upon adventitious circumstances for their sustentation; each, however, let it always be reverentially remembered, performing an important duty in the scheme of infinite goodness and wisdom, far beyond our judgment to fathom.

It would be to us a delightful task to trace the march of intellect from the earliest writers on the natural history of this and other portions of nature down to the present time; to enumerate the various lights thrown upon its study by the unwearied exertions of learned men; and to sum up the moral and physical benefits mankind derive from it; but time and space prevent our doing so. We can, therefore, only sketch a very faint outline of the advance this science has made, in defiance of all the difficulties that surround its study and retard its progress, in the way that has marked all the other portions of the animal kingdom, since of those to whom an opportunity is afforded of seeing these animals, but a small number possess the requisite knowledge to give a correct description of their structure, and travellers' sights may easily be magnified into marvellous tales when resting only on the creative evidence of imagination. We, nevertheless, most earnestly recommend our readers, at all periods of life, to pursue a knowledge, always easily attained, of some one branch of nature, not only as an endless source of the highest rational enjoyment, combined as it were with the development of a new sense of feeling, but, as we firmly believe, beyond all other pleasures conducive to render them happier because better men, through the instruction every page of nature affords to those who are willing to read it in the simple language of truth and piety. How admirably has the poet said that there are

Tongues in trees, books in the running streams,
Sermons in stones.

But a mind unused to examine or reason upon natural facts, perceives neither beauty or novelty in the wonderful changes silently going on around us daily; their uniform progress having been from the beginning of time, is always coeval with ourselves; and, without a necessity for our active interference, the senses become imperceptibly reconciled to their regularity, an indifference is engendered to the phenomena of nature, they take place and pass away, leaving no impression behind them, when viewed, as they but too frequently are, as things of course, with which we have nothing to do. When, however, a spirit of scientific inquiry is roused, a taste imbued for the investigation of nature's operations; when the energy of the mind is once applied to trace, as far as may be, the effects of general causes, to attempt an elucidation of some of the laws by which these are governed, every living thing then assumes a new aspect: at each step fresh matter for wonder and reflection presents itself; we behold all the mysterious effects of chemical combinations, all the powers of mechanical principles, every thing that governs matter or motion, exercised in nature to a degree of perfec-

tion, compared with which the proudest work of human ingenuity is at best but a pitiful imitation; and we are thus taught to believe, upon the evidence of our known senses, that the most trivial difference in the uniformity of nature's economy is, and must be, the result of given physical powers, to which all parts of the machinery in some way contribute, under the guidance of the great Master's hand, variously stimulating the numberless tribes of animated nature, each after its kind, *not by chance*, but according to the predestined purposes of their existence, all subservient to vain-glorious man, and every one manifestly illustrative of the omnipotence of that supreme wisdom, which directs and governs the whole, ordaining a perpetual harmony of system, in order that the extinction of life shall not be felt, and the devastations of time become supplied by succeeding generations.

This not being our present purpose, we will pass over the monstrous stories of an era darkened by ignorance and superstition, though many of them, when divested of their fiction, give evidence of having been founded on natural observations, since confirmed to a certain extent; and we will take our starting point from that period when the greatest of all naturalists, Linnæus, formed his imperishable monument of nature's history, the *Systema Naturæ*. It would be consummate arrogance and affectation in us to deny that any other can be formed with greater accuracy, taken as an original whole; but it is not in the power of man to define a complete, much less a perfect, system; and we should be wilfully blind, or close our eyes to truth, were we not to attempt an improvement upon it with the immense facilities since afforded us, and by that extension of the human mind to which no bounds can be placed, though at last far from attaining all its bright dreams. To the present day, many exist who would deem it worse than treason to dissent from the laws of Linnæus, and bold must that man have been who first dared to throw off the shackles of prejudice and deeply-rooted early habits, in order to exercise for himself the dictates of reason, when they were in opposition to so great an authority. Such men were, however, found as naturalists; and, though for many years the study of nature's productions was almost exclusively confined to the Continent, we must not forget, in the admiration so justly due to the illustrious names of Swammerdam, Fabricius, Pallas, Adanson, Müller, Poli, and a host of other eminent men, that we have Lister, Hunter, Munro, Willis, Leach, and many others of our own time, who lent their learning and contributed largely to the same good cause. As English naturalists, they must come in for their share of that information which has led to the mighty results, more recently communicated to mankind, of the subject we are now more particularly upon, by the unwearied and triumphant efforts of nature's chamberlain—Cuvier. Such men, like comets, are few and far between; but their course is marked in more enduring characters, and the track they have pursued will never be effaced from the annals of science. To the gigantic mind of Cuvier, modern naturalists gladly cede the palm of superiority, and the period is not yet calculated when another shall eclipse his well earned fame.

He possessed, it is true, a rich store of other men's laborious research, with an education fitted to the proper use and understanding of that treasure; but he commenced the labours of a naturalist under most adverse auspices; these did not, however, deter him

from his leading passion, and he finally became what he was, through a patient and wearisome course of new and difficult observations, aided by an enthusiastic love of his subject, and the well directed strength of a powerful mind, determined to exercise its own dictates, though they militated against the long established homage paid to previous authors, whom he, nevertheless always admired as his superiors. His conversations and intimacy with nature, if we may be allowed that trope, might well have rendered him vain-glorious; but, on the contrary, his life, his writings, every thing relating to his biography, and the intercourse we happily enjoyed personally with him, prove him to have been an unassuming humble-minded man, open to conviction, and not despoiling information from the meanest source. This then is the man chosen by common consent as a guide for systematising our present but little understood order of natural history. The imperfection of the Linnæan system in this branch was manifest, and a reference to the article CONCHOLOGY will point out some part of its errors; but as it is no difficult task to find fault, though a very difficult one to amend, until within the last half century nothing beyond suggestions of improvement were cautiously thrown out; till at length Cuvier, profiting by them, and undismayed by the difficulty of the task, determined upon remodelling the old system, forming on its ruins a new superstructure, which included the molluscous animals without a calcareous protection, as well as their more numerous relatives with one, clearly demonstrating the folly of making a separate arrangement of shells from their inhabitants, or forming a system of parts of the whole order, any more than might have been done with the scales of fishes, the feathers of birds, or other integral portions of the same animal, whatever its rank in natural science. In this he took nature for his guide, most ably following the indications she always presents, for a systematic arrangement of her works. Having already stated that we shall pass over the intermediate minor steps of gradual improvement, and alteration which had taken place prior to the present arrangement of molluscs, we will attempt to describe the system as it now stands, sanctioned by every enlightened mind, as the only true basis of Malacology. To do this it will nevertheless be useful that we should rapidly trace some of the most important corrections, or *innovations*, as they have been termed by the disciples of the old school.

Daubenton, in 1748, read a Discourse to the French Academy of Sciences, of which at that time he was not a member, pointing out a methodical distribution of the shells of molluscous animals; in this he attempted to show that a knowledge of them was not sufficient to guide the systematic arrangement of their inhabitants, and remarked that a more extended examination of their anatomical structure was indispensable to form a more natural system of conchology, even according to the then established rule of Linnæan science, he did not, however, act up to his own suggestion, by pursuing these notions so justly formed.

In 1756, Guettard, a member of the same learned body, appears to be the first who acted upon the hint given; and though his dissertation was supposed to be an implied satire on Buffon's writings, he clearly pointed out the necessity of having recourse to the animals constructing these dwellings, in order to come to a right conclusion respecting the dwellings themselves, he accordingly introduced many very important

corrections of the old system. These new lights furnished by Guettard may probably have determined d'Argenville to publish, in 1757, a new edition of his Conchology, adding a great number of badly executed plates of animals, under the name of *Zoomorphoses*.

In the same year Adanson applied Guettard's system in a much more extended point of view in his account of a Voyage to Senegal, naming, with great precision, all the external parts of the animal as well as those of its envelop, and drawing very philosophical conclusions on the relative connexion between them both; but, unfortunately for science, he only applied his arrangement to the shells of Senegal, and did not attempt to form a system generally upon that basis.

Another French naturalist, Geoffroy, profiting from the same hints thrown out by Guettard, and so ably seconded by Adanson, in his description of the terrestrial and fluviatile mollusca in the environs of Paris, 1766, gave an admirable definition of the animals as characteristic of the arrangement of their shells.

Müller, the celebrated author of the *Fauna Danica*, was the first zoological writer who adopted a similar principle in his description of terrestrial and aquatic worms; his system, although more complete than that of Geoffroy, is still very unnatural, and inferior to that of Adanson.

It is about this period that a change in Linnæus's *Systema Naturæ*, with regard to molluscous animals, became obviously necessary. In the nine editions of that work, he had not named the molluscs at all, the naked animals we now so designate being distributed as worms in his class of the *Zoophytes*; and such as were covered with a shell furnishing his third order of the same class, under the name of *Testaceæ*; but in his tenth edition, great augmentations were made; and in the twelfth, which may be considered the last that underwent the revision of that great man, many more were added. This, was published in the years 1766, 7, and 8; and it is to be remarked, ten years after the hints of Adanson had been thrown out, by which Linnæus doubtless benefited, he, nevertheless, in the characters of his genera confined himself to mentioning an analogous mollusc; and if the work of Adanson materially affected his system, it was only then exhibited by an alteration in his genera of shells, properly so called, without leading to any positive confession of the knowledge of their inhabitants being essentially necessary to his arrangement. The impulse given throughout Europe by the labours of Linnæus, seconded to a great extent by the writings of Buffon, occasioned several naturalists to publish anatomical descriptions of molluscous animals.

Fabricius, Müller, and others may be cited, and, in order to disturb as little as possible the long established school, every effort was made to reconcile the organisation of the animal with its covering.

Pallas may therefore be considered the founder of a new school, and of that new systematic arrangement which has progressively gone on in improvement till it now is acknowledged to be the best and the most natural. In his *Miscellanea Zoologica*, 1766, he proves that Linnæus in the arrangement of his molluscous worms, had wandered widely from nature. That his subdivisions of shells, as admitted by the naturalists of his day, could not stand; in consequence of his having considered their configuration only, without a reference to the animal, he therefore proposed to unite the two as forming a more natural order.

Bruguiere, an author of modern times, who has

contributed more largely than any other to the science of malacology up to that period, does not, however, appear to have reaped all the advantages he should have done from the labour of his predecessors, and though he has made some very necessary changes, he, for the most part, was contented to follow their general principles.

Gmelin, who published an edition of the *Systema Naturæ* of Linnæus in 1789, which was about the time of Bruguiere's writing on the subject of worms in the French Encyclopædia, although he had an opportunity of consulting all the newly-broached ideas on the subject, has scarcely varied in any very important feature from the twelfth edition of Linnæus.

But in 1791, the celebrated Italian physician and anatomist Poli, was the first to publish the genera of molluscs according to the organisation of their structure without any reference to their testaceous covering, which up to that period had only been partially effected in some genera; no one previously possessing either nerve or talent enough to propose such a plan as generally applicable to every similar creature; but he only confined his researches to the molluscs of the two Sicilies; he there divides the animals into three orders; under the name of *Mollusca brachiata*, he characterises all such as have numerous arms, including consequently the *Sepia* of Linnæus; in the second order, *Mollusca reptantia*, all such as possess the faculty of climbing by means of a large foot, and having a head and eyes like the common sail, and most of the univalves; and thirdly, the *Mollusca subulenta*, including such of the molluscs as possess a large foot by which they are affixed or not, to rocks and submarine bodies, but constantly devoid of a head or eyes. This order included the bivalves and multivalves.

Thus, down to 1796, the science of malacology had been making progressive steps towards its present state, aided, as we have before stated, by the labours of other eminent naturalists in all parts of Europe; but as they had only worked upon the system of those we have shortly mentioned, they merely as it were assisted in navigating more easily the old vessel, without venturing upon a new model for themselves. From 1789 down to 1798, a period of nearly ten years, the science of malacology appears to have remained nearly stationary.

Cuvier, whose scientific labours, though fettered, had never been subdued by the convulsed state of political occurrences, then appeared on the stage, and commenced the foundation of the prodigious improvements he has since accomplished. Justly feeling, with those naturalists who had preceded him, that a natural and methodical arrangement might be effected of molluscous animals, upon the same principles as those which guided all other natural productions, namely, the study of their organic structure, he proposed the classification which now is received as the nearest perfection, by being the most closely drawn from Nature's precepts. He first of all imagined that molluscous animals should be placed a degree higher in the scale of creation than they had previously occupied, and precede those animals which were externally articulated, though internally without hard parts, such as insects. The next innovation on long established custom was, upon the suggestion of Pallas, to unite definitely under the classical name of molluscs, the Linnæan molluscous order of worms, with the testaceous order; considering the existence or absence of a calcareous covering as

not affecting such an arrangement, or only viewing it as a secondary point; he therefore formed a distinct class of the immense group to which he still continued the name of animals with white blood; subsequently named invertebrated animals. Looking in the next instance at the anatomical structure of these creatures, he divided them into three grand sections, naming them—*Cephalopods*, or possessing feet in the head; *Gasteropods*, as having feet in the belly; and *Acephalophora*, or being without heads. In the first he placed the Linnæan *Sepiacea*, adding some other genera, since reformed. In the second, and by far the most numerous section, were included all such as had to that period been described, but separated according to the old-fashioned notion of naked molluscs and those with shells; and the third section was divided into five divisions, according to the formation of the shell. As this first attempt has since been considerably improved upon, we will not enumerate the different genera constituting these divisions, but proceed onwards in our rapid sketch of the progress of malacology. We have in this instance mentioned enough to prove that Cuvier pursued the plan Pallas had suggested, including also the alterations proposed by Bruguiere, Lamarck, and other of his contemporaries.

In 1799, Lamarck read to the French Institute a programme of his new classification of molluscs. In this he acknowledges the labours of Bruguiere and Cuvier with regard to the animal structure; but he was from that cause obliged to multiply the genera by an addition of sixty-two, constituted from those they had enumerated in their works, with a few others not known to them previously. It is evident that Lamarck, following the track of Bruguiere and Cuvier, did not at first exercise that broad independent judgment which, in 1801, was exhibited in his work, "*Des Animaux sans Vertébres*."

In the same year appeared the work of Audoubert de Ferussac, the elder, in which he also describes the genera, from an examination of the animal in relation to its habits: his plan, however, subsequently underwent great changes.

In 1802, Bosc, in a supplement to Buffon's works, admitted the necessity of these new changes; but he, nevertheless, retained the two Linnæan distinctions, or divisions, of the naked molluscs and those with a testaceous covering: in those he closely followed Bruguiere's method, but included all the generic subdivisions established by Cuvier and Lamarck. It is but justice to Bosc to acknowledge, that having had great facilities in examining molluscan animals in their native element, he has ably availed himself of the opportunity,—establishing some new well-defined genera, and introducing several facts in the natural history of these animals totally unknown to other authors.

In 1803, Draparnaud published a prodromus of the terrestrial and fluviatile molluscs of France, which did not appear until after his death in 1808; he also added some new genera, and particularly introduced the change of nomenclature with respect to the parts of shells, always viewing them as a part of the animal, and describing them as moving before the spectator, being, therefore, the first to abandon the Linnæan laws on that subject; otherwise his classification corresponds with Cuvier's system.

De Monfort commenced a work, afterwards completed by De Boissy (forming a portion of Sonnini's

edition of Buffon), that, generally speaking, harmonised with Cuvier, and, like his predecessors, he introduced new genera, and altered the arrangement of others. The science of malacology is, however, greatly indebted to his researches, in having introduced a general distribution of the microscopic shells observed by Soldani, Von Moll, and Von Fichtel; he also proposed a great number of new genera, so ably constituted that they have been preserved in modern malacology, though under different denominations. His nomenclature for the most part being gratuitous, he did not attempt a classification of his genera with reference to the animals; and, like the very small molluscs he principally described, his distinctions are so minute, that the more or less angular form of the aperture—the presence or absence of an umbilicus—were sufficient to establish separate genera. In the univalves, which was the only portion he had methodically classed, this is strikingly manifested, for, out of thirteen genera of chambered molluscs, which was all that other authors had described, he formed no less than 100—eighty-seven being entirely new, according to his plan; it is needless to add that his arrangement would have been interminable, and included almost as many genera as species.

Another work, embracing many new ideas, is the Analytical Zoology of Dumeril, published in 1806. In this he adopts the method of Cuvier, in placing the molluscs before insects; but he divided them into five orders, adding a new and ill-assorted one which he named *Brachiopods*.

In 1809, Lamarck, obliged by his distinguished post of Professor of Natural History, to follow the progress of science, and to point out every new fact connected with that study, proposed a new distribution of those animals, adding a class he named *Cirrhipods*, which, at the present day, may be considered as an intermediate link between the molluscs and the articulated animals. Keeping pace, therefore, with the new discoveries of Cuvier, Peron and Lesueur, Lamarck again, in 1812, published another edition of his work, greatly improved and enlarged. From that period during the three ensuing years, gradual advances were making towards completing a system founded on the anatomical structure of mollusca.

In 1815, Oken appears to have been the first who entirely abandoned the Linnæan arrangement in his system of malacology; but few new genera were added, and even those of Lamarck curtailed; but his work is remarkable for the changes he has made in substituting new names for old ones, and thereby adding to the difficulty of the study.

In 1817, Cuvier published *Le Règne Animal distribué d'après son Organisation*, a work which combined all he had previously written on molluscs, adding much valuable new information towards the completion of a natural system of malacology.

In the following year, Lamarck commenced the publication of his second edition of *Animaux sans Vertébres*, to which he added the previous information derived from the researches of other authors, and particularly a work of Dr. Leach on the *Nematopods* and *Cirrhipods*, &c., in which he characterised several new genera adopted by Lamarck, as were others suggested by Sowerby in the fossil genera, which in every instance are extremely interesting as connecting links of the great chain of natural affinities, marking the extraordinary mutations this planet has under-

gone, and furnishing evidence of facts which, without a knowledge of them so conveyed, would have rendered the geological phenomena of nature a far greater mystery than they now are. In this great work, Lamarck has very accurately described a vast collection of molluscs, and doubtless would have gone on to a greater extent, had not the loss of sight obliged him to depend more upon the descriptions of others than his own. To a naturalist, the loss of that precious sense must be fatal; but we can only say that the errors it has occasioned in some parts of Lamarck's work are less in consequence and fewer in number than might be imagined under such a cruel affliction. During the period occupied in completing this work, malacology had everywhere received an impetus, and many eminent men in various countries contributed their researches on this interesting subject. In Germany, the works of Schweiger and Goldfuss on molluscs particularly merit notice. In America, those of Say and Lesueur. In Italy, Rafinesque. In England, Donovan, Leach, Sowerby, and many others. But these for the most part applied their attention to the conchological arrangement of mollusca.

Leach, about 1821, commenced a description of English molluscs, based upon the anatomical structure of their inhabitants, and would doubtless have perfected his labours, had not a cruel malady for a time deprived science and his friends of that benefit. His views in all he did were philosophically correct, and we are happy to add, that his health being perfectly restored, we may yet hope to derive instruction from his writings, as a recent letter from him mentions that he is busily occupied in collecting and describing the entomology of Italy; he does not indeed say for publication, but we trust such is his intention. In 1822, Gray published, in the London Medical Repository, an article which, however, may be considered little more than a translation of Lamarck's classification, changing their denominations; his observations at that time on the opercula of molluscs, which he has more recently embodied, are extremely interesting and highly important in the study of malacology. De Férussac the younger, who had occupied himself principally with the terrestrial and fluviatile molluscs, with a view to extend and complete the work his father commenced, wished also to attach a general system of malacology to these molluscs, but we cannot admire the scheme, and it abounds with discrepancies. As a work of art it is a magnificent one, and equal to anything yet published in graphic verisimilitude. Having thus, with a rapid course, traced the outlines of improvement effected in malacology by naturalists, down to the period at which the system has taken a pronounced shape, by De Blainville and other writers, we will not stop to enumerate the subsequent valuable information derived from the detached labours of a number of eminent naturalists, too numerous to be here mentioned, whether as anatomists or zoologists; but in thus acknowledging the obligations of science to them generally, we trust we shall not be thought invidious in mentioning particularly the name of Mr. Richard Owen, Professor of Comparative Anatomy, R.C.S.L., whose early career as a zoologist is stamped with so much excellence, that well-founded hopes may be entertained of his becoming our English Cuvier, should health keep pace with his mental exertions in the study of natural creatures. A want of space, as we have constantly reason to regret, now fetters our wish to have made a more minute chronological

history of the writers on that part of malacology which embraces descriptions of the animals only; and we must, therefore, proceed to give an outline of the system we have adopted as our guide, with some general account of the structure of these extraordinary animals comprised under the name of molluscs.

It is scarcely necessary to say that the mollusca are found abundantly distributed over every part of the globe's surface—in the seas, rivers, sands, forests, and plains. Their number is incalculable, and the form of their bodies is beyond every thing extraordinary, and would baffle any attempt at a description of most of them, with regard to a clear definition of any shape approaching mathematical symmetry; they, however, possess some general features which are fixed and constant. They are never articulated; generally of an oval form, more or less elongated; sometimes convex above and plane beneath, sometimes convex above and below; the sides often compressed, and others greatly attenuated. In a great proportion of the cephalopods, the upper part of the body is spirally rolled in the form of their covering, and some are so singularly constructed that no intelligible account can be given of their figures without seeing them before our eyes; but we never admit the unphilosophical term of a shapeless mass to any thing in nature, *form* resulting from *purpose*, and that defined by *matter*. A great number of these animals exhibit a distinct separation between the head and the body, as in the *Sepia*; it is less marked in the *Doris*, a specimen of which is here figured; and in some

Doris cornuta.

the head, properly so called, does not exist in a distinct form; from which cause they are called *Acephala*, or headless animals. The distinction of neck, chest, abdomen, and tail, is still less evident; the body presenting merely a mass united, or sometimes subdivided vertically, but never as it were split in a direction from the front part backwards. The bodies of these animals are very rarely furnished with locomotive appendages, properly so called in other animals; but they sometimes possess cutaneous expansions, more or less developed, which assist progressive motion, and it is only in the articulated molluscs that these parts assume a form more analogous to those of insects. The skin which envelops their bodies is constantly soft and spongy, so that it is contractile in every direction, in this is situated the colouring pigment, which is often of a vivid colour. It may be supposed that the mucous cysts, or concealed cells on the superfiice of the skin are extremely numerous, judging from the large quantity of matter distributed generally over its surface; but it is frequently very difficult to discover them. In some species the mucous pores are more evident. No true hairs are found on these animals; sometimes, however, the epidermis of the shell is prolonged externally as it were, and presents a fringed or hair-like appearance, observable in some of the helices and bivalves. In some species of the *Chitons* this is very remarkable, for these calcareous horny points are frequently placed in small tufts on both sides of the body. As it frequently

occurs that the skin of these animals is larger than necessary merely to surround their bodies, or the visceral mass exactly, and that its plaits appear to envelop it, the name generally adopted for this portion is *pallium*, or the mantle, to designate the skin of molluscs, though in fact this does not always exist so disposed; so various is the general position of that mantle, that we shall not attempt a description of the differences, as it would lead us beyond our limits. The edges of the mantle vary exceedingly in form, some of them being lobated, or more or less digitated, the protection of which characterises the form of the *Pteroceras*, and other molluscs, familiarly said to have claws; but the most singular property of the mantle is that of secreting, in addition to the colouring, a cretaceous matter, whose accumulation and desiccation forms a protecting cover, or shell properly so called.

In the article CONCHOLOGY we have explained, to a certain extent, nature's operation in this respect, illustrating it by the easily observed process of the snail, is the formation of its dwelling; our present object is therefore confined to the anatomical organisation of the animals constructing shells, without reference to the shells themselves in a conchological point of view. The apparatus and sense of touch appears to be seated in the tentacula, or tentacular cirrhi, with which the edges of the mantle are generally furnished; and it is probable, from a parity of reasoning, that certain tentacular appendages, occasionally in the form of a fringed membrane, as in the *Janthina*, may be considered as organs of touch, as well as serving for organs of locomotion. In some molluscs the organ of taste is not at all defined, as is the case with all the *Acephalophora*, in others it is only a lingual mass, ill defined; but in some species that mass is provided with small hooks and spines on its surface, closely resembling the tongue of some of the feline mammals, and leaving no doubt of the purpose of that organ; this is visible in the snail. The organ of smell has not yet been positively determined, and a great diversity of opinion exists upon the subject; some have thought, from the texture of the skin of molluscs, they possessed the faculty of smell dispersed over its whole surface; but as the sense of smelling can only be accomplished by the odour of the particle of matter smelt being free to escape through the medium of air, this sense is only given, in all probability, to such of these animals as breathe air, and is seated at the extremity of the true tentacula, where the skin is invariably softer, more smooth, and in every respect of a more delicate texture than any other portion of the animal's body; the nerves are also more numerously congregated at that part. The organ of vision does not admit of so much doubt as many other of the senses, because the connexion, cause, and effect, is more easily remarked and determined; the headless molluscs do not possess eyes, neither do that class called articulated molluscs; and here, as in every other instance upon which an opportunity of reasoning is afforded us, the wisdom of Providence is manifested most strikingly.

If the organs of locomotion are always distinctly defined by a true muscular fibre, visible on the internal surface of the skin, which is there disposed in a tendinous bundle, of a determined form and disposition of parts, and even sometimes is attached to the most solid portion of the animal's body, the numberless other contractile fibres with which molluscs are provided assist also, in all probability, to their locomotion; but as it is so difficult to see these crea-

tures in their habits, considerable uncertainty exists as to the precise part of their body which serves as legs in all the species. In the *Cephalophora*, the name of foot has been given to a muscular disk, or round substance of greater or smaller thickness, situated at the extremity of the animal's body, and produced by a prolongation of the muscular fibres. In some molluscs, the so-called foot extends the whole length of the body, forming a kind of sole; by means of which the animal is enabled to climb, which, occupying the surface of the viscera, has occasioned them to be called *Gasteropods*, or *Reptantia*, meaning animals with feet in their belly; but in such species as from their form are specially rolled within their shell, and their congeners, the foot or sole does not cover the viscera, but merely extends from that part which separates the head, and may therefore be called the neck, which has occasioned them the distinctive name of *Trachelipods*, or having legs in the neck; the proportionate size, and even the form of this foot, varies very considerably, even in examples of the corresponding genera: thus, in the *Patella* it is nearly round; oval and very thick in the *Halotis*; rounded in front, and gradually becoming thin on either side, in the *Murex*; ear-shaped in some of the *Terebra*, and a great number of the order *Cyclostoma* and in the *Conus* it is divided by a transverse groove at its anterior edge. All the species of paracephalous molluscs, without shells, are eminently gasteropod, but that is not the case with those possessing shells; they are not, nevertheless, trachelipods necessarily, although that most usually is the case; but a fact common to both is, that these muscular fibres are always so placed with regard to the shell, that they can be contracted to a greater or lesser depth within it, as well as the head itself, by means of a muscular bundle, denominated the muscle of the columella—because in spiral shells it is always attached to that part. The form of this muscle and its disposition differ considerably according to the form of the foot, and more particularly with respect to the configuration of the shells. To this columella muscle also, belongs the power of opening or closing the aperture of the shell, by means of its operculum, when that appendage exists. In the *Cephalopods* and *Paracephalophora*, which are sometimes provided on each side with numerous locomotive appendages, as in the *Sepia*, *Calmar*, and their congeners, and generally indeed in the *Pteropods*, or winged molluscs, these parts possess depressing or elevating muscles attached at their root to the back or the belly; but when these do not serve to perform locomotion, they are merely formed of a contractile skin, in which no muscles are distinguishable. In the acephalous or headless molluscs, in the centre of the abdominal part is situated a muscular mass, more or less thick, which, besides its external, possesses internal contractile muscles, and this mass is in them called the foot, similar to that occupying the lower portion of *Gasteropods*; the shape and size of this varies very considerably, till in some species no trace whatever of it exists, as in the oyster. This foot is attached more or less in front of the body, which depends upon the habitual position of the animal, but it can also be used in different directions, by means of true muscles divided into a greater or smaller number of bundles, directed towards different points of the shell, particularly backward, forward, and sometimes towards the intermediate space, as is the case with the *Onodon* and its congeners. This extensible foot sometimes as-

sumes the shape of a sucker, as in the *Nucula*; a lingual appearance, as in the mussel; in the *Venus*, the form of an arc; and in the *Chama*, the form of the human foot. Other muscular portions of the animal's body, in conjunction with that termed the foot, occasion by their attachment to the shells of bivalves what is called the muscular impressions, serving, when well defined, to guide the malacologist with considerable truth in determining the order of the animal they enclose. In the locomotive system of bivalve muscles, their mode of articulation, by means of an external, internal (and in some species both combined), ligament, that part must be examined with particular attention, as aiding or acting as an antagonist to the adductor muscles. It is formed of transverse horny fibres, which in their natural position connect the valves, but constantly tend to keep them open by their elastic nature, like a spring, occasioning the animal no trouble in opening its shell, and not requiring the body to be provided with another set of muscles for that purpose. This is a simple and beautiful provision of nature; the general wants of the animal requiring its shell to be more frequently open than closed.

A very singular fact, observable in the tendinous bundle of muscles forming the foot, is that some species possess the faculty of becoming agglutinated and attached to submarine bodies, serving as an external point of resistance or repose. This constitutes what is termed the byssus, that substance not being, as many authors supposed, a filamentous excretion, contained in a given gland, and spun out by the animal's foot, but it is a continuation of the fibrous muscles, one portion of which is living in the animal and possessing contractile powers, while the other, attached to the object serving to fix it to that spot, has become devoid of sensation, and incapable of feeling the injury it would otherwise have sustained by collision with different bodies, had its sensibility been preserved externally as it is internally. Another extraordinary provision of nature which we cannot here pass over unnoticed, which, however, wants the positive confirmation of the preceding one, is the apparent probability that the animal possesses the faculty of changing the position of its adductor muscles, in proportion as it increases in size; for if, in a shell not having attained its full period of maturity, this muscle was central, it must, to retain that position in the animal's body, move backward in its points of adherence when it attains a greater growth. This is illustrated in many bivalves; we will instance the most easily to be examined—the oyster, in which the muscular impression indicates a change of position very distinctly marked of the subcentral muscle, not that it need be detached all at once to effect this, but probably because an anterior arrangement of muscular fibres become detached as a posterior set are produced, the use of the one being no longer necessary, or kept in the activity of health, lose their energy and as it were die off. No certainty is yet acquired on this head, but it has given rise to much speculation, and various extremely ingenious opinions.

In the *Lepadicea*, no locomotive organs, properly so called, can well be admitted, they live and die on the spot which gave them birth; and the *Chiton*, in its locomotive parts, approaches very near to the true mollusc, the whole of the lower part of its body being occupied by a species of foot, very analogous to that of the *Patella*, &c., while its shell possesses

as many double pairs of oblique muscles placed on the right and left sides as there are testaceous portions. The powers of locomotion depending always upon the necessity of existence under the various positions of animal life, it is evident, with regard to molluscs, that it must be extremely restricted in most, and even not necessary at all to many. Whatever creature is gifted with the greater number of senses, it also possesses the better organised muscular system to exercise the purpose of those faculties; thus, the *Sepia* roams at large in pursuit of that first of all necessities—food, while the *Ascidia*, possessing fewer of the senses, remains permanently fixed to submerged bodies. We may, as it were, sum up the nature of locomotive evidences in molluscs, and give a few conclusions drawn from such facts as have fallen under the naturalist's notice, incomplete and in many instances uncertain, resting only upon analogous reasoning, but satisfactory as far as such can be. Various kinds of locomotion exist in mollusca; some direct their movements by means of symmetrically placed appendages acting as oars, using them much in the same way as fishes employ the fins, and these organs sometimes enable them even to spring into the air to a considerable height, which is witnessed in the *Calmar*; a similar operation is said to be effected by some species of bivalves, whose expanded valves are employed as points of resistance in the water. Another kind of natation is occasioned by a very compressed foot alternately moving from right to left, as it is seen in the *Carinaria*, but this always takes place in a reversed position, that is, with the back beneath and the belly uppermost. A third, yet

Carinaria—the shell of its natural size—and a reduced figure of the animal with the position of the shell on it.

more singular, has been observed in the *Sepia*, *Calmar*, &c. This is performed by a sudden contraction of the envelope of the animal's body, by which the fluid contained at the moment of its complete extension is expelled, or spirted out, giving an impetus which is directed by means of the muscular appendages of the body in the direction required. Some molluscs float on the surface of the water, propelled as chance may direct by the caprice of wind or waves, supported by means of a vesicular apparatus, as in the *Ianthina*; and the *Argonauta* is elegantly described as having an inhabitant which navigates its frail bark by means of an extended portion of its mantle, and guided in its course by oar-like muscular appendages; a reference to that article will more fully explain this assertion, and the other still contradictory opinions respecting that mollusc, and the shell it inhabits.

Some terrestrial molluscs progress by lifting the anterior part of their body, and bringing up in tolerably quick time the posterior part or foot, at the same moment making a well marked step forward. A very large proportion of molluscs crawl on the surface of the earth, or in the water, by the aid of a foot or muscular disc, with which their belly is furnished; at this kind of reptation differs widely from that of reptiles; it is rather a species of gliding forward, produced by the rapid succession of the extremely minute undulations composed of muscular fibres, forming that part called the foot.

It results from this species of motion, by which every inequality of the ground or other substance is touched as the animal passes over it, that the advance is by no means rapid, and under any circumstance of excitation cannot be materially increased; though the slugs and others of their class, whose foot is very large, thick, and wide, get forward with greater despatch than might at first be imagined; and the absence of a shell to carry must doubtless render their motions more easy. Some, on the contrary, whose foot is always very large, as the *Patella* and *Haliotis*, move so slowly, and so seldom change their resting-place, that many naturalists have erroneously supposed them constantly stationary; respecting these, we have under their names pointed out another fact, that of the power they possess of adhering with immense force to the object upon which they rest. The *Hyponyx* and *Capula* remain fixed to one spot during life; and the foot, not being actively employed in them, is scarcely to be called muscular; it more nearly resembles the horse-shoe-formed muscle which attaches the back of the animal to its shell. The *Scyllæ*, whose foot is extremely narrow, and as if channelled, cannot without great difficulty move on a plane surface; but can with perfect facility and even speed, climb the stems and peduncles of marine plants; its progress is, however, completely sliding along them; this is, doubtless, assisted by the medium of water rendering the objects they are found upon smooth and easily passed over; to compensate for which the slugs are abundantly supplied with a lubricating fluid secretion, which enables them to slip over the minute dry substances that would without that wise provision encumber or clog their foot. The common grey slug, here figured, will readily explain this kind of locomotion.

Limax cinereus.

Those species of molluscs, which can ascend in water, do so by making the water a point of resistance; but they are then compelled to reverse their natural position. The shell is beneath, and the underside of the foot upwards; this is exhibited by the *Lymnæa*, *Planorbis*, *Paludina*, and others. This last mode of locomotion is but rare in the acephalous molluscs, though one or two instances have been given upon good authority; something analogous may be supposed to exist in the *Nucula*. Judging from the arrangement of the

foot, the movement of this class is often totally confined to the inconsiderable expansion of their valves. With regard to locomotion in molluscs, generally, the first circumstance to be considered is the natural position of the animal while in a state of repose, for it is only at that moment their food is supplied to them in the water, particularly when the mouth of the animal does not possess extensible tubes; the expansion of their valves in a greater or smaller degree governing the quantum of food, or the convenience of receiving it: we have already explained that this is constantly effected without any effort on the animal's part, by means of the ligament or spring connecting the valves; the act of shutting the valves being effected by the adductor muscles acting as antagonists against this ligamentous fastening. Leach and some other malacologists have imagined that a part of the central adductor muscle was formed of an elastic substance in the oyster and other bivalves; but it is not confirmed by subsequent observations, and therefore seems doubtful. The family of the *Palliobranchiata*, or such as have their branchiæ situated on the internal part of the mouth, or the pallium, exhibit examples of genera in which, instead of a ligament, the two valves are united at their summit by a long elastic tube affixed to sub-marine bodies, being in some cases slightly contractile; the animal, however, enjoys no other movement than the opening and shutting of its valves, like other acephala. In the species of molluscs fixed by their shells or by a tube, these being the only motion possible, a very simple organisation of foot is either requisite or visible. In the other species more locomotion exists, though still to a very limited extent; they are not, in fact, fixed by the immediate contact of the shell with another object, but by fibres or a byssus; and though they have the power of fastening this dried muscle, and as it were anchoring themselves to a solid place by its assistance, yet they cannot voluntarily detach themselves from that fastening; the method employed to affix themselves is by means of the very long extensible foot, particularly characteristic in the byssiferous molluscs.

The *Tridacna*, *Arca*, &c, have also the faculty of attaching themselves to solid bodies by an agglutination of the foot; but, unlike the byssus, it is in mass, and not in separate fibres. In by far the greater number of molluscs without heads, the power of locomotion is more extended; the use of the foot in its proper office is, that of aiding their removal from place to place; some merely exercise it in ascending or descending the hole in which they have fixed their location, whether in wood, stone, mud, or sand; their foot being attached more anteriorly than in the other species, is more readily extended, and takes its point of rest at the bottom of the cell: this always takes place in the *Pyloridea*, whether tubular or not. All other bivalve molluscs, although they often live more or less buried in the mud or sand, can always quit it voluntarily, or move to any other spot; some perform locomotion by means of leaping, the foot serving as a spring, and acting in the same way by its contraction and sudden relaxation; from this mode of motion, the name of *Subsistentia*, or leapers, was given by Poli to the headless molluscs, but evidently erroneously; for if the greater part of the animals of this family of shells possess that power, the *Arks* and others do not, but are permanently fixed, and appear really to climb with their foot.

The *Chiton* moves in a crawling position by means of its abdominal foot, much in the same way as the *Patella*.

The *Lepas* and its congeners, as we have already stated, cannot quit the spot upon which they were born.

The apparatus for nutrition is much less known than that of locomotion; but it appears complete in all the molluscs, consisting of the organs of digestion, respiration, and circulation; a very small number of molluscs are able to seize their prey before introducing it into their mouths—these are the *Brachiocephala*, or such as have those singular appendages like arms, or tentacula, fixed at the top of the head; with these they lay hold of or entwine the living animal they are about to swallow. In molluscs, whose buccal orifice is furnished with teeth, they appear to possess the power of masticating or crushing their food as well as seizing it with them. When one tooth only exists in the upper part, it serves as a fastening to the object upon which the tongue acts; this is clearly exhibited in the common snail and other species of *Helices*. But little is yet known of the trunk or proboscis with which some molluscs are provided; the teeth they sometimes possess at their extremity, may possibly serve to drill holes in the shells, which contain their sustenance, and through them they suck the juices by means of their trunk. The use made of the spiral tongue in the *Chiton* and certain *Patellæ* is quite unknown, at least, with any degree of certainty; but little more is known of the manner the acephala derive their nourishment; it would appear that it is most generally in a molecular form, suspended in the water, which is conveyed to the mouth by means of the appendages surrounding that part; for they indicate no appearance of salivary or masticatory organs.

The *Palliobranchia*, assisted by their long labial appendages, must more readily seize their food, since they are capable of extending them beyond the shell, and moving them in every direction. Deglutition must go on as it is effected in the higher orders of animals, at least we know it does so in the cephalopods. With regard to the digestive organs of molluscs, that process is probably carried on very slowly; nevertheless, the slug and snail, which are those we can more readily observe, eat ravenously during an abundance of their favourite food, which would imply a very active digestion, as few creatures eat more than will suffice for immediate want. Digestion is, doubtless, in these as in other animals greatly assisted by the action of bile, which generally is abundantly supplied, to judge from the size of the liver, the number of vessels receiving it, and the size of the hepatic canals; in fact, the bile is often poured into the stomach itself, or at the pyloric orifice. If, as it appears certainly to be the fact, acephalous molluscs receive their aliment in a molecular or microscopic size, the action of bile must be very secondary, as digestion cannot require its assistance, and in this group of animals the liver is very inconsiderable. We know nothing certain respecting the chyle; but it is, doubtless, absorbed in the intestinal canals. The respiration of molluscs is carried on under similar circumstances with that of animals in a higher grade; we know that oxygen is absorbed by them from the air they live in; but whether solely by the organs of respiration is not so certain; indeed, it is extremely unlikely, the general envelope of their bodies being so absorbent; but as the organ of respiration contains

a far greater number of vessels than any other part, the breathing of air must at that point be chiefly conducted. We know also by experiment, that those species furnished with a pulmonary cavity soon die when immersed to a certain depth in water, without it being possible for them to gain the surface; and, on the contrary, the species with branchiæ cannot live long in the open air, particularly when the branchiæ are exposed; but when these are internal, the animal can exist for a considerable period, by means of the moisture humecting them, and by its slow evaporation.

The mechanism by which the ambient fluid is brought in contact with the fluid medium, or blood of molluscs, is simple and well understood. In those species whose branchiæ are external (as the *Tritons*, &c.) the animal has only to swim in order to breathe; those, on the contrary, such as the *Pulmobranchiata*, where the respiratory organs are contained in a cavity—like, also, nearly all the paracephalous molluscs—the air or water is introduced or driven in by the dilatation or contraction of the cavity, and of its plain or tubular orifice, and these two effects are facilitated in all the species, particularly those furnished with a shell, by the extension or the contraction given to the anterior part of the body at which the apparatus is placed, and by its advanced position into the larger part of the shell, but in no one instance is there any regularity of inspiration or expiration. It does not even exist in the *Brachiocephala*, where the water, introduced into the cavity of the mantle in which the branchiæ are, assists, at the same time, for locomotion. The headless molluscs, which are all of them aquatic, present nearly the same mode of respiration, the labial appendages, by their continual movement, determining a sort of current in the water in which the animal is plunged. It may easily be distinguished in such species, the extremity of whose mantles is prolonged into two tubes varying in length, the water entering by the one beneath, and passing out by the other above; thus respiration takes place when the fluid traverses the branchial cavity. It is suspected that the effects thus produced on the blood which fills the pulmonary or branchial arteries are analogous to those of animals more elevated, but that cannot positively be ascertained, because there is no physical distinction between the arterial and venous blood of molluscs. In the circulation of blood, the progress of blood through the veins seems nearly as slow as that of the arteries; neither have they any true pulsations, although the heart exhibits regular movements of the systole and diastole; they are, however, very slow, but can easily be seen in the acephalous and cephalous molluscs.

The mode in which nutrition is carried on in molluscs, by the aid of external and internal absorption, is not more known than in the other classes of animals; that which appears certain is, that these animals can support a long fast, particularly when their bodies are completely sheltered by means of a shell, of which the snail is an example and proof; neither does this animal, like many others which hibernate, possess any internal supply of fat, that substance not existing in any mollusc; what is so called in oysters being nothing more than a peculiar condition of the ovarium.

Molluscs possess the extraordinary power of reproducing in a very short time, under favourable circumstances, certain external portions of their body, destroyed by accident or other causes, which may easily be conceived with respect to the mantle and other parts; it becomes, however, less easy for

olfactory tentacula, and, above all, for the ocular ones, whose organisation is much more complex, but with regard to the animal's head, including the brain, such a thing is to us quite inconceivable, notwithstanding the solemn assurances of some writers to that effect. We have indeed been asked why the experiment was not made by ourselves, to which we reply, that it has been made by others; and when such men as Muller, Bonnet, and Spallanzani, entertain a contrariety of opinion on the subject, we feel no inclination to shake our conviction by useless cruelty and needless experiments. The functions of decomposition or exhalation in molluscs nearly resemble that of the higher animals; general exhalation, which is much more abundant in the aerial than in the aquatic molluscs, appears but little known; it is probably more passive than active. The particular exhalations constituting the secretions and excretions are rather abundant. We have already spoken of those which form the shell in such as possess it, as also the liver and salivary glands, employed in digestion.

The means of reproduction in molluscs is not known to us in its full sense, and the investigation belongs to the physiologist. Nothing whatever is positively known of the duration of life in molluscous animals, from the impossibility of watching their progress while in a state of freedom, surrounded by the accessories necessary to their development and preservation, but it may be inferred from the length of time necessary to mark their growth that they live long; dwelling also as they do in a medium, and in situations less subject to the changes of atmosphere or various causes that influence the existence of other portions of creation, it is but reasonable to conclude that the measure of their life is less acted upon by extraneous effects, and that they attain to greater ages in proportion to these advantages than any other branch of animated creation. We do know that they possess the power of multiplying their kind to a countless extent, and wherever that exists in creation, great tenacity of life is generally observed as being necessary to keep up the useful purposes they are destined to perform, which invariably are more numerous than in those animals which multiply their race slowly and in small numbers. No species of molluscs, even of the most perfectly organised, exhibit any positive appearance of sympathetic associations, or the slightest mutual attachment, beyond each instinctively seeking the most favourable situations for their development, growth, and comfort.

We pass over that part of the physiological structure of these animals but little understood, and only interesting to a class of persons who will seek it from higher authorities than ours: we will, however, describe some interesting facts regarding the eggs of molluscs, founded upon the observations of long experience, and many of them not generally known, from the same cause that has and ever must retard the progress of our knowledge in this department of nature—we mean the difficulty of watching their operations in their native element. The eggs of nearly every mollusc are mucous, and more or less of a horny texture, but in some of the terrestrial species (the *Bulinus*, *Achatina*, &c., for example) they are covered with a calcareous shell, rendering them in appearance similar to those of birds, and of some reptiles. They are sometimes cast or laid in a congregated free mass, in which they are united in several ways; but sometimes they are deposited singly, and

attached to marine bodies by means of a stem or pedicle, which occurs in the *Buccinum*, *Purpura* and its congeners, and the females of the ovoviviparous molluscs lay their eggs in small numbers during the season of fine weather. In the eggs, here figured, of

Eggs of the *Argonauta*.

the animal found in the *Argonauta argo*, they resemble a bunch of grapes. In the terrestrial molluscs the eggs appear always sessile, often separated, or merely laid in a heap, and often united by a viscous matter which forms them into a mass. These eggs are generally deposited in situations the most favourable to their future development, and though a very small number of molluscs appear to entertain the slightest kindness for, or take the least care of their progeny, some such feelings may be said to exist in the *Voluta gondola*, the young of which, according to Adanson, are gathered together during some time in a fold of its foot, probably as they quit the oviduct. The *Janthina*, also, deposits its eggs around the parent shell; common snails lay theirs invariably in favourable situations for their best attaining maturity, and the more easily meeting with a supply of naturally wholesome food the moment that want is experienced by a new state of vital existence; and the mollusc always found in the *Argonauta* constantly deposits its eggs at the bottom of the shell. The *Balani* possess the power of placing their eggs by means of the long trunk which terminates their oviduct; but most molluscs lay their eggs by hazard, and the viscous matter usually surrounding them enables their position to be stationary on those spots in which they were first excluded. Various experiments have been made clearly establishing the great vitality of the eggs of molluscs, some of which, after having been five months exposed to the burning sun of a tropical climate, and others to the artificial heat of an oven, and repeatedly dried in it, have not lost the property of future development.

Of the habitat of molluscs, they may be said to exist in every part of the globe, buried in the impenetrable depth of the sea—on the surface of the earth,

Testacella halliotea.

and even one species, the *Testacella halliotea*, here figured, under the ground: some of them are to a certain

extent amphibious, being capable of breathing air by the organs of respiration, yet living in water which they rarely quit voluntarily, such as the *Lymnæa planorbis*. The greater number constantly inhabit salt and fresh water, being incapable of existing out of it; these distinctions are anatomically defined in the aquatic and terrestrial species, possessing a particular structure of respiratory organ; but it is not so easily observed what characters distinguish such of them as possess branchiæ of the same structure, and are capable of existing either in salt or fresh water with the same ease, or only in the one or the other. The location of marine molluscs is extremely various; a great portion of them live on the sea-coast, on rocks, in the sand, or at the embouchure of rivers; these are called *littoral* species; others are only to be found at a distance from the shore in great depths of water; these are called *pelagic*; others, as we have already stated, float on the surface of the waters, or attached to various submerged bodies. Others live in the sand or mud; some make a dwelling in wood or stone. But it is almost needless to observe that the terrestrial species are much less variable in their habits, and that it is generally in moist places that they are most plentifully found; some, however, seek a dry soil for their habitation, and, under the disadvantageous circumstances to their comfort of too much heat or too great cold, they conceal themselves under ground, in the holes of trees, or other sheltered spots, where, during the noxious season, vitality is for a season partially suspended; and they hibernate like some others of the animal creation, remaining in a state of torpor the whole time, from which, however, they may be roused, though the experiment ill-conducted would occasion instant death.

The species of nourishment necessary to the existence of molluscs varies according not only to the nature of their formation anatomically, but greatly also with respect to their localities. They subsist either on animal or vegetable substances, dead or alive, fresh, or in a state of putrescence; but each species, each genus even, and yet more certainly, each family, confines itself to one or other of these nutriment. All the known CRYPTODIBRANCHIATA, the *Sepia*, *Octopus*, &c., seek their food in living animals, which they tear to pieces, by means of the hard parts of their mouth; and in that state probably swallow them without further mastication. The SIPHONOBANCHIATA, the *Murex*, and its congeners, appear all of them to be carnivorous; it is not likely, however, that they often swallow their prey whole, they may suck it by means of their toothed trunk, or otherwise reduce its substance, but they cannot masticate it, being unprovided with true organs for that faculty. The ASIPHONOBANCHIATA, *Trochus*, &c. seem to be less generally carnivorous, perhaps not at all so, taking their food, either animal or vegetable, in a putrid state, their proboscis-formed trunk being more adapted to sucking than masticating, this is certain with regard to the terrestrial *Cyclostoma*. The PULMOBRANCHIATA, *Lymnæa*, *Physa*, &c., are, on the contrary, decidedly phytophagous, or vegetable feeders; they cut and masticate the food they subsist upon in small pieces, which they swallow by slow degrees; they possess a mouth provided with one tooth of a cutting shape, to which is opposed the lingual mass; it is however asserted that the *Testacella* swallows whole worms, drawing them gradually into the intestinal canal. The CHISMOBRANCHIATA, *Sigaretus*, &c.,

with the MONOPLEUROBRANCHIATA, and *Berthella*, probably feed in the same manner as the asiphonobranchia, since they possess no appearance of teeth in the mouth. The PTEROPODS, *Alalanta*, do not appear to have the power of mastication, for the above reason, and merely take their food by suction. The same may be said of the CYCLOBRANCHIATA, *Doris*, &c., and even generally of the POLYBRANCHIATA, *Glaucus*, &c.,

Glaucus Fosteri.

though in this last order there are some genera, such as the *Tritons* and *Scyllæa*, in which two jaws exist,

Scyllæa pelagica.

acting laterally like scissors, enabling them consequently at least to cut or separate their food in small portions. The NUCLEOBANCHIATA, *Carinaria*, *Pterotrachia*, appear to feed upon small animals; the CERVIBRANCHIATA, *Patella*, probably do the same, but the greatest portion of their nourishment is most likely derived from decomposed matter. In all the class of *Acephalophora*, *Terebratula*, *Lingula*, &c., the same mode of feeding is obviously necessary, since their mouths, being entirely soft in all its parts, cannot make the slightest impression on any substance possessing consistence, which seems to confirm the idea that they only subsist upon animal or even vegetable particles, resulting from things, in a state of decomposition, conveyed by the fluid element which enters into the cavity of the mantle destined for respiration; neither is it impossible to conceive that they may derive a great portion of their nourishment from the innumerable microscopic animalculæ existing in the water they inhabit, which, being of the greatest softness, require no masticatory process for preparation as food.

From the nature of the aliment, and the very different circumstances under which it is obtained, it is equally evident that molluscs must employ various methods of supplying the first want of nature. Those species which, like the *Sepia* and even the *Testacella*, prey upon fugitive animals, pursue, catch, and destroy them; when impelled by hunger, some wait for their victims, lying in ambush, displaying a bait or temptation formed by some portion of their weapons of destruction, and exercising in this operation a degree of what is termed instinct, very similar to that of animals of a more exalted grade in creation.

Others who subsist upon living objects, in situations where their prey from local habits or necessity are to be found constantly situated, penetrate the shell by drilling a hole with their toothed proboscis, and have consequently but little trouble in seeking a commensurate supply of nutriment; and with such as are not permanently located to one spot, the trouble is somewhat greater; but when once attained, a supply of food lasts a considerable time, and other objects are not far distant to replenish the store. Molluscs living upon animal or vegetable decomposition, no doubt discover it by the sense of smell or feeling, and have also but little trouble in finding it. This is the case with those which, like the greater part of the slugs, feed upon vegetation, in a more or less solid state of life; with these it only requires their being cut into small portions and swallowed. In short, for all the species whose nourishment depends upon molecules of matter, or invisible minute animated beings, no necessity exists for the labour of searching after them, the customary motion of their organs producing a vortex, into which the food is drawn, and probably swallowed with the fluid itself, as it flows through the animal's structure.

The diseases of molluscs cannot any of them either be studied or accounted for beyond the general conclusion—that a want of proper food or accident has occasioned a disordered state of action. The first must very rarely occur in an element teeming with animation, adapted to the immediate supply of that imperative necessity; the latter, also, is less likely to happen, from the strong defence nature has wisely provided, to secure them from external injury, or the attacks of enemies. Both these events, as we have shown, do nevertheless occur; and thus, by the laws of nature, one animal becomes the prey of another.

In some bivalve molluscs, which are the most frequently known to us as articles of food in our markets, a visible difference exists in what we term their state of growth and condition of appearance; they have even some of them their season, but we can in no way satisfactorily explain what peculiar state of disorganisation they labour under, or why indeed any moment of time should render them better than another, except that period which in oysters has been ascertained to be the time when the office of reproduction is in activity; and they, like all other creatures, suffer from its operation.

In the *Sepia*, and the first class of the *Cephalopoda*, we have shown that they possess a more perfect system of organisation than any other of the molluscs, not only with regard to the development of animal senses, but also as respects the exercise of them, it being a well established fact that they use occasionally what in the higher orders of creation would be termed cunning, in attracting and seizing their prey. The intelligence they exhibit decreases, in proportion as the animals of this tribe descend in the scale of organisation, till it arrives ultimately at that point when it ceases to a mere mechanical operation, and is only confined to the opening or shutting of the valves of their shells, as in the oysters and other numerous species of that type. The general sensibility, or rather susceptibility, of the molluscs—that is, the sense of touch—is strikingly manifest in all of them, every portion of their structure being most delicately formed, so as to receive the slightest impression, externally applied, and different from that state of re-

laxed or unexcited period of repose they enjoy, when not actively employed in the exercise of their several functions; but this sensibility is more particularly situated at the edges of the mantle, which are very often furnished with tentacular organs, of exquisite susceptibility; these are clearly distinguishable in the conchyliferous *Paracephalophora*, and also in the two lobes of the mantle of all the *Acephala*. The oyster, for example, may be observed to close its valves, merely by a sudden impulse being given to the water in which it lies. This sense becomes less apparent in many species, whose exterior envelope being always exposed, is less tuberculous; and in those whose skin is more or less hardened by exposure, it is scarcely to be observed at all.

A friend, whose modesty will not allow us to name him, but whose scientific knowledge we have more than once gladly availed ourselves of, well knowing its accuracy and judgment, has favoured us with some facts connected with this subject, founded upon repeated experiments and the most certain data; with his permission we here insert the result of them:—"The form of the mouth, so called, in molluscs, varies extremely in its character, and it requires some experience in these singularly organised creatures to distinguish it at all in many species. Nevertheless, it always exists in some form or another, depending greatly upon the figure of what we may term the lips, or surrounding muscles, these also possessing no given permanently fixed character, except as regards generally each species; they are, consequently, very different in the distinct classes or groups. In the most perfectly organised, the *Sepia* for instance, these lips resemble a folded circular membrane, of great delicacy, pierced in the centre, and asymmetrically fringed at the edge. In the *Tethys*,

Tethys leporina—lower and upper sides.

the *Doris*, and the *Patella*, the lip forms a thick semi-circular band, and at the centre of its lower side the opening of the mouth is placed; this is sometimes carried out laterally, and forms a tentacular appendage. In the *Triton*, the front edge of this thickened band is dilated and fringed, forming a membranous curtain varying in its size; sometimes these lips are prolonged into the shape of a cup or glass, at the bottom of which is the tongue, or trunk, this is the case with the *Conus*. Within these lips, which are contractile in every part, and closing many of them like the opening of a bag drawn together, there are found in some species hard or corneous portions, which the

French naturalists have erroneously called jaws ; they are more properly to be designated teeth, performing their functions, and their structure and mode of formation are exactly similar to teeth. In the *Sepia*, these teeth act in direct opposition,—in the *Triton*, hori-

Triton Hambergii.

zontally, in which case they are then surrounded at their base by a thick circular muscle, pressing them against each other when acted upon by the animal in feeding. In the common snail, there is only one tooth notched at its top, and it appears to serve as a purchase, upon which the lingual mass or tongue of the animal acts, not possessing any muscles to give it action of itself, and remaining stationary for the time required by the animal to eat, or rather lick the object affording it sustenance, for which purpose the tongue is admirably adapted, being thickly set with small corneous bristles somewhat hooked, and of the character of the tongues of the feline race. In ripe fruit or other vegetable matter, this fact is clearly demonstrated. In the *Bulla*, the hollow internal cavity of the mouth, the upper part or palate is armed, like the tongue, with minute corneous teeth. The headless molluscs have no appearance of teeth whatever, but the aperture of their mouths presents the character of a lip, which is often prolonged into a tentacular appendage."

In the classification of molluscs, so as to form a system of malacology, by the proper distribution of their species, the same rules may be applied as with every other type of animated nature ; it is quite clear that nothing short of the whole organisation of any animal can guide a naturalist in pronouncing the proper order, class, or family, to which it belongs, by affinity of parts ; and that the external characters of the organs in these creatures must equally furnish their distinctive positions in a systematic arrangement, as with animals more exalted in the scale of creation. In malacology one great distinction may, however, be drawn ; the general organisation of the animal is often well characterised by the form of its shell, and that indication has induced many naturalists of the old school to imagine a knowledge of the one sufficient to acquire the other ; but this error we have endeavoured to rectify in the article before us, and we will now add some further proofs of the fallacy of that opinion, and of the necessity of taking many other objects into consideration, to which end we cannot do better than quote extracts from the opinions of Cuvier, Lamarck, and other naturalists, who have founded, and brought to its present state of perfection, the system of malacology ; but we shall only do so where those opinions concur, and are sanctioned by living naturalists, as the differences that have, and must always exist on matters but little known and difficult of access, could not either interest or instruct that class of our readers whose minds are only dawning to a love of the study of nature and the Almighty giver of life ; such as have advanced more deeply into that delightful pursuit, having overcome its first difficulties, and seeking to discover more from the inexhaust-

ible store it presents to an inquiring mind, must either look for assistance in the detached labours of scientific men who are pursuing a similar course, or strike out for themselves an untrodden path : our pleasant task is ended, when we have, to the best of our ability, amassed together everything we deem usefully instructive in this branch of natural history, and condensed it to the smallest space capable of conveying our meaning, or that of the high authorities we have quoted.

A consideration of the precise spot or particular country inhabited by molluscs can be of very little importance as a guide in their classification, as their locality is not indicative of the form of the animal or its scientific arrangement. We cannot, like the good old Isaac Walton, say, while walking by the river side, here we will rest and take a shell of such a description, as he was wont to say of a chub or a trout, without having a previous knowledge that such things were to be found at that spot. The peculiar kind of subsistence these animals require cannot either have much influence, because, though it is possible to imagine a certain correlation of organs visible, and the structure of the digestive apparatus more or less modified for some one particular alimentary substance, that never is the case, as far as every examination or reason can extend, and we have indeed a proof that no such provision of nature exists, since we find species essentially carnivorous, as the *Testacella*, of the same order as the slug, which is completely herbivorous. The existence or absence of a calcareous protection or shell, is evidently of very considerable importance to a scientific arrangement, since that constitutes a well-defined apparent external character ; a knowledge of them will, however, furnish proofs, though the exceptions are not numerous, of conchyliferous animals being of the same genus as others completely divested of shell, such as the *Bulla* and the *Lobaria*, the *Bursatella* and the *Dolabella*.

The particular form of the animal's body, where the visceral portion is more or less spirally elongated, is also of very little importance, as we have seen examples of the snail, in which the whorls were drawn out like a watch-spring, not touching each other in their convolutions. The lobes, cirrhi, and other appendages, which border the mantle, are not very important to consider, if we except the order *Lamelli-branchiata*, where a consideration of the tubular lobes, by which the mantle is prolonged backward, present extremely useful characters. The animal possessing a perfectly or imperfectly formed head, or none at all, constitutes the different divisions of the first order of malacology ; but these characters are not always very distinctly defined. The form, position, and number of the tentacular appendages of the head, present a more essential and certain character to study in the establishing a classification of molluscs ; some anomalies are nevertheless observable and altogether inexplicable ; in the *Carychium*, for example, the true tentacula gradually disappear, while other animals of the same family have them strongly produced. The position of the eyes is a consideration of some consequence, but probably less so than the tentacula, nevertheless it forms no constant guide, as genera of their family, and even species of the same genus have subpedunculated eyes, and others have them sessile. The principal organ of locomotion, that is the foot of the animal, and the natatory appendages, are of very considerable value in classification,

Nautica Labyrinthus

Nautilus angustatus

Pteroceros scorpion

Chione dione

Murex Roseus

from their position and shape; and their characters being external, it is not surprising that they are so frequently and so advantageously employed in malacology.

A better guide still might be found with regard to its importance in many essential points of consideration, that is the armature of the mouth, either at its orifice or in its interior, because that would immediately enable the naturalist to pronounce, with considerable certainty, the nature of the animal's habits of feeding in general, but the difficulty of the examination has doubtless deterred the most able zoologists from using it more frequently as a law of arrangement in the system. Another character, still more preferable possibly with regard to its great importance, because it accords extremely well with the form of the shell, may be drawn from the position, the form, whether symmetrical or not, and even the structure of the organs of respiration. But here again, unfortunately, it requires no small anatomical skill to employ this character, though they are most frequently nearly external, and the shell, where it exists, peculiarly adapted to their protection. But the part of organization in molluscs, perhaps as important to consider as almost every other, is the generative apparatus composed of the two sexes, but separate in that structure of each, united both of them in one sex, or only existing in females; here again the examination is entirely anatomical, and very difficult to apply to a system of malacology.

The form of the testaceous covering of molluscous animals is certainly extremely important as an accessory guide to the malacologist; it must, therefore, be well considered, and taken in its various grades of useful information. The first consideration we would point out is the number of pieces or parts which enter into its formation, univalve, subbivalve or operculated, bivalve, tubivalve, or multivalve. Secondly, its position on the animal's back—dorsal, as in all the CEPHALOPODS—dorsal and ventral, as in a small proportion of the same order, and of the ACRPHALOPHORA—or bilateral, as it is in all the LAMELLIBRANCHIATA. Thirdly, the indices it furnishes with regard to the organs of respiration; that is, the existence of a channel or tube at the anterior extremity of the aperture in univalves, or of a gaping or separation, more or less considerable, of the posterior extremity in bivalves. Fourthly, the information it affords respecting its connexion with the muscular system of the animal, which constitutes what are termed the muscular impressions, simple in univalves, and only visible in the *Patella*, *Halotis*, &c.; more or less complex in bivalves, and formed, as we have explained, in this article, by one, two, or even several adductor muscles, one or more retractor muscles of the foot, the marginal or parallel ligula, the mark of attachment of the edges of the mantle, and backwards by the impressions of respiratory tubes. Fifthly, the form, whether symmetrical or not, which determines a similarity or a variation in the parts of bivalves. Sixthly, the form of the aperture in univalves, and the manner in which each side of the columella or its vitreous deposit contribute to form and modify it. Seventhly, the ligament and hinge of the two portions of bivalves, that is the position and form of the ligamentous fastening, and the position, number, and shape of the so-called teeth of the hinge, observing particularly that each true species of mollusc has its special and almost constantly undeviating form of hinge and teeth, as in

the *Arca Noë* and the *Glycimeris*, here figured, in

Arca Noë.

which a different arrangement for example is visible. Eighthly, a very important and strongly defined character, now more extensively consulted from being better known through the light Gray and other modern writers have thrown upon it, is the presence or absence of an operculum, its form, and, most particularly, its structure; this furnishes, whenever it is known to exist and can be examined, a clear, strong,

Glycimeris.

and unobjectionable proof of the class of molluscs, which is external and undeviating in all its characters of the same species. In the numbers of shells we have examined we have never found any of those anomalies existing in the operculum, or those singular freaks of nature which other portions of molluscs frequently exhibit; their characters are simple and uniform. It is constantly attached to the foot of the animal possessing it, at the upper or lower side, closing the aperture of the shell completely, either at its opening, or more or less internally distant from it. Some authors—Adanson of the number—have considered it analogous to one of the valves of a shell, but its position, with regard to the animal's body, decidedly contradicts that opinion: the two valves of a bivalve are placed one on each side of the animal's body, in almost every instance, while in the operculated molluscs, the shell alone, dependent on the mantle, occupies its dorsal side constantly, and the operculum never has any connexion but with the upper or dorsal part of the animal's foot, sometimes at the angle of its junction with the pedicle of the body, rarely at its posterior extremity, and most frequently midway. It is evidently the product of the skin which covers the foot, and is, doubtless, an excretion of horny or calcareous matter, but how a plain surface of an oval or circular shape can produce a matter whose molecules are spirally rolled or laid on a flat surface, often with great regularity, sometimes

forming many turns or evolutions, and constantly alike in number in the different species of molluscs, is a question not easily to be answered with any degree of conclusive satisfaction; we might quote several opinions of high authority, but as they are contradictory, and resting upon the speculation of ingenious theories rather than upon anatomical data, we consider them foreign to our present purpose, which is to point out well-established facts, and not to launch into doubtful ones. The subject is, however, worthy of the naturalist's serious consideration, and we shall be happy to find this suggestion worked upon by those whose leisure will permit them to pursue it; and, in that study, much interesting information may be gleaned from Mr. Gray's publication on the subject, which we will not mutilate by abridgment here. The operculum of shells must not be confounded with a calcareous covering put on under peculiar circumstances by molluscs, to guard their bodies by closing the aperture of their shells, as it totally differs in its formation of parts, substance, and position, with regard to the animal, it is distinguished by the name epiphragm, and is very often seen during the winter on some species of *Helix*. Ninthly, the combined form of the shell, the proportionate length of the spire, and the shape of the opening in univalves, with its direction, and various shaped parts, as in the *Columbella mercatoria*, here figured. In bivalves,

Columbella.

the proportions of the valves on either side, their markings and sculpture, and even their colour, the presence or absence of an epidermis, with any other clearly defined distinction of its whole appearance.

According, therefore, to this rapid detail of the considerations necessary to guide the malacologist in distinguishing the various molluscs, with a view to their scientific classification, the importance their relative characters offer in the different portions of their organisation, and the necessity of examining attentively their shells, to a certain extent, in order to assist by the evidences they furnish of the animal's structure, Conchology, as it has heretofore been termed, is not altogether useless, though it is not by any means indispensable. As, however, an examination of the beautiful armature of the animal may in many cases lead to a more scientific acquaintance with the place it occupies in the scale of creation, the formation of conchological collections should receive every encouragement.

The basis of an arrangement which now embraces both them and their wonder-working architects, must be founded on the general form of the animal's body, the distinction of a more or less well-defined head, or of none at all, and the organs of respiration which modifies the shape of the shell, observing, always, that the same configuration of shell sometimes, though rarely, is represented by very distinct genera; this, for example, is exemplified in the *Haliotis*, whose form exists in the pulmo-branchiata, in the cismo-branchiata, and in the otidea,

is the same with the patelloid, turriculated, and other forms. These are the principles that have guided Cuvier, Lamarck, and their disciples in the classification of molluscs, and formed that system which is now universally adopted by naturalists of the present day, or at least such of them as have kept pace with the extended knowledge of the age we live in, and the surprising facility given by accurate, elegant, and cheap publications in every branch of it. Before we proceed to give some outline of this system of malacology, we will shortly state some of those principles by which the distinction of species may be facilitated—a part of the science by far the most difficult in all the types of animal creation, but particularly that under present consideration, arising greatly from the circumstance of the shell having been made the only guide for their distinctive separations or divisions, and the determination of making them contribute to the cause, without overturning altogether the Linnæan school, in so far as its principles could consistently be adopted, and made conformable to the far different view now taken of this subject.

In the construction of a system, the great master, Cuvier, has distinctly laid down some general rules, to which it will be well always to attend, though they are not always applicable; in objects like the present, our knowledge does not extend far enough to pronounce without doubt on the singular structure and less known habits of molluscs, we must therefore approximate the species carefully and consistently, according to the most obvious external organisation in relation to the habits of the animal; should these agree, one principal step is gained in forming a genus; and the smaller differences form an after-consideration, and establish the basis of consistent sub-divisions.

Cuvier says, "That the formation of systems is the object of natural history, properly so called. Anatomy receives them as it were ready made. The latter takes its first direction from the former; but it is not slow in reflecting back the light it has received. By applying a system of natural history to comparative anatomy, we are speedily enabled to discover whether it deviates from the path of nature. The object of every good method is to reduce a science to its simplest terms, by reducing the propositions to the greatest degree of generality of which they are susceptible. A good method must, therefore, be such as will enable us to assign to each of its subdivisions some qualities common to the greater portion of the organs. This object is to be attained by two different means, which may serve to prove or verify each other; and that to which all men will naturally have recourse, is to proceed from the observation of species, to unite them in genera, and to collecting these in a superior order, according as they find themselves conducted to that classification by an examination of the whole of their attributes. The second, and that which the greater part of modern naturalists have employed is, in the first instance, to fix upon certain basis of division, agreeably to which, beings, when observed, are arranged in their proper places. The first mode cannot mislead us; but it is only applicable to those beings of which we possess a perfect knowledge; the second is more generally practised, but it is subject to error. When the bases that have been adopted remain consistent with the combinations which observation discovers, and when the same foundations are again pointed out by the results deduced from observation, the

two means are then in unison, and we may be certain that the method is good."

We will proceed to explain shortly the system we have now adopted as our guide in malacology, and it will be necessary to point out some general principles to assist in discovering the distinctions of species, the most difficult part of all the branches of natural science, but most particularly in this above the others on account of the shell having so long been considered the only guide for the distinction of species; and as

before remarked, the indications given by the structure of the shell must supply the information we want, where the anatomy of the animal is totally unknown, as for instance the *Aspergillum*, here figured, is classed as following its congeners, the *Gastrochaena*, *Clavagella*, and others of the family *Pyloridea*, from characters common to all of them; though it is difficult to assign any reason or use for the perforated holes in the disc of its lower end, without they are to give a passage to the fibrous muscles of the animal's foot, in the character of a byssus, by means of which the animal affixes itself to submarine bodies, in a situation more or less vertical, the smaller extremity of its tube above, and the head of the animal downwards; this is at present merely conjectural, the animal not being known. The species of any one series of animals cannot correctly be determined without taking into consideration the anatomical structure of the apparatus of generation, and particularly its accessory parts, although a strict coincidence may exist or not in the other parts of organic structure. These latter are not always so essential from the dubious circumstance that they are frequently only observable in such parts as cannot be called organs possessing an use, but no functions such as shells. This principle may be rigorously applied to mollusca, since all the true species that physiologists have examined in a very large and numerous genus, the *Helix*, for example, there has always existed some important difference in the generative organs of course much more marked in the separate sexes, as is evident also in the *Murex*, *Buccinum*, &c.; those distinctions are additionally defined by the size of the shell, which, in the females, is always of a greater capacity than that of the males.

Adanson, who has devoted much time to the study of molluscous animals, assures us that even other parts of the animal, such as the lobes, and the appendages of the mantle, vary considerably with age, the period of the year, and consequently the shell also, whose differences are not confined to the colour, its being smooth or rugged; its thickness, its size, the development of its various bands or tubercles; but that they extend likewise to the form of the opening, and the proportion of other parts. If, therefore, the sex or age present an evident influence in determining the distinctions of molluscous animals, and consequently their shells, it is not less evident that in appreciable circumstances may influence, in a smaller degree,

the animal; and in a larger degree, the shell, whose colour, proportions of size, and different parts, vary remarkably in different examples of the same species. This may be observed in the *Helix nemoralis*, *Lymæa stagnalis*, and others we have an easy opportunity of examining in confirmation of this fact. By a parity of reasoning, we may readily imagine, that a variety of circumstances, to a certain point appreciable, such as climate and locality, have decidedly influenced for a series of time, and almost as it were upon fixed principles, the succession of individuals of the same species, in their size, colour, &c., and even in the form of their opening, and the peculiar characters of their superficies, compared with others precisely of the same genus, living for centuries in an opposite locality.

This may be termed the geographical distribution of species, very marked certainly in many instances, but, in truth, not really affecting a scientific arrangement; for it invariably happens, that when these varieties are assembled, we find them range insensibly with each other, and thus form but one family. This is exhibited in the *Cerithium*, whose species differ so greatly in their external form, but all possess the same generic characters of structure. A most interesting but difficult scheme might be formed of these insensible gradations in every reign of natural history, proving indubitably the unity of general purpose, exhibited in them all, according to their peculiar duties and stations in the scale of

animated nature.

A minute examination of living molluscs is also indispensable to the geologist, as it mainly guides his conclusions in furnishing a good natural guide in resolving the problem of the analogous strata of secondary and tertiary formations. The connexion between molluscs and the geological structure of the earth is extremely manifest and highly important, for without seeking to ascertain here the difficult fact, whether shells have borrowed from inorganic matter their bases, or, as we think, contributed to effect the marvellous changes produced on the surface of the globe by their decomposition and masses in various stages of existence; one thing is quite clear, that the manner in which these deposits are made, differs essentially in various places, and under various circumstances, according principally to the habitat of molluscs; whether beneath the sand, or mud, or free in the bosom of the deep; thus, the oyster in all countries forms beds and banks of various extent and thickness, horizontally placed, in which at this moment they remain precisely similar to the position they occupied in former ages, and almost without any other admixture of different bodies; this fact is less evident in many other of the mollusca; but all the genera of molluscs living in the sand or mud, vertically placed, must of necessity form beds of their spoils, since the increase of number is made by a deposit of the newly-born above the parents, who in course of time become buried by their own offspring, and,

Aspergillum.

Cerithium.

by rendering the distance between them and their source of food too great to be reached by the limited extent of their organs, are thus starved to death, these shells, which were when living *vertically* placed, assume gradually an inclined position by the superincumbent weight and the undulating action of the water, are filled with sand or any other matter in which they lived, forming those vast beds of fossil shells which are everywhere existing in the earth's formation, unbroken and even preserving all their delicate characters. Other molluscs, whose motions while living are unconfined by any thing but local convenience or other circumstances inducing them to remain within a limited range of locomotion, are not ever buried in the sands permanently; and their shells after the animal's death, becoming the sport of the winds and waves, are indiscriminately rolled from one spot to another, or broken against the rocks and corals of a submarine world, until they are reduced to molecular portions, in their turn assisting in forming new strata, in which the law of specific gravity is manifest, the heavier portions forming the most dense beds, the lighter being uppermost; thus keeping up that compensating plan of infinite wisdom, which has established that all things created shall for a time perform their several functions of creation, then pass away, yet continue under other forms, to be necessary to succeeding generations, each of their kind whether animal, mineral, or vegetable.

We shall not, perhaps, be deemed visionary in saying, that it is by these beds, these deposits of calcareous matter, which in a long series of years, and the continual pressure of others above them, combined with the tendency of inorganic molecules, to solidify, and even crystallise, that many rocks have been formed, which now present no trace of their ancient organic structure. On this subject we promise our readers some interesting information, under the article *POLYPUS*, in which the coral formations will be described, and found strictly illustrative of our present geological view of the earth's formation, neither must the sceptical advance an opinion of the impossibility of such being the fact by the limited number of molluscs we know of, since they form but a trifling portion of those we know nothing about, or have only seen a few of, amidst the countless myriads with which the depths of ocean teem, whose spoils of former races have accumulated slowly but surely during the lapse of ages, beyond the power of man to calculate with certainty. Molluscs exist, and ever have existed, in all portions of the globe, no part of it being without its tenants, whether on the surface or beneath its elements,

Where the pool
Stands mantled o'er with green, invisible
Amid the floating verdure, millions stray;
Each liquid too, whether it pierces, soothes,
Inflames, refreshes, or exalts the taste,
With various forms abounds. Nor is the stream
Of purest crystal, nor the lucid air,
(Though one transparent vacancy it seems,)
Void of its unseen people.
Let no presuming impious railer tax,
Creative wisdom, as if aught was formed
In vain, or not for admirable ends.
Shall little haughty Ignorance pronounce
His works unwise, of which the smallest part
Exceeds the narrow vision of her mind.

Their numbers consequently depending upon the range of locality; and though we should feel disposed to assert that species of the same family are probably to be found in almost every climate—such

as the *Sepia* and its congeners—they certainly are far more numerous in some countries than others, being naturally influenced like every other animal by those circumstances most conducive to its development, growth, and life.

As our knowledge of this interesting class of animal existence becomes daily more and more unfolded, we have in the same proportion increased cause to adore the inscrutable wisdom which has dictated their formation, and given to them important functions, all tending ultimately to benefit mankind, and acting unseen in their operations, beyond such as must be ascribed to them in common with creatures more elevated, but not more useful, in the scale of nature. We have slightly digressed from the plan we had proposed; but the animal and its testaceous covering being so intimately united in our point of view, we could not pass over the one without mentioning the other. We said that the true principles of malacology might be best founded upon a certain organic structure, but in this as in every other part of systematic arrangement, the task must rest with experienced zoologists, and very properly so, as systems are intended for masters, more than disciples, as a *whole*, though indispensable to the latter as an authority and instruction, in matters where knowledge can only be derived from such sources, generally unaccompanied by an opportunity of judging their correctness beyond a very confined portion of the subject. There is another well defined character upon which the French naturalists particularly have founded their system of malacology, it is more easily examined, and presents the most satisfactory conclusions with regard to the present possibility of classing the naked with the clothed molluscs, under one general distribution of classification. It is the *Respiratory Organs* of molluscs; from which the denominations of the different orders derive their names. In the system we have adopted, as the most natural and most complete yet formed, harmonizing too with the characteristic structure of the shell wherever it exists. As it is obviously necessary that a work like the British Cyclopædia must be based upon some generally acknowledged system, as applicable to the different branches of natural history it explains, we have determined upon that which is universally now followed by writers on malacology, having found their judgment fully corroborated by our own experience; and though as we have and shall continue to point out anything not strictly correct, or any new ideas that subsequent information and daily discoveries enable us to mention; it is taken altogether, as perfect in its principles, and as good in its classification as it can well be, for no system can be quite so, or indeed ever complete; the very nature of our inquiries leading to new results, and carrying on those of other persons to a far greater extent than they had observed or had mentioned. The late eminent Dr. Woollaston once told the author of this article that steam, and the application of its powers to mechanical purposes, was but in its infancy, and mighty as its operations now are, they give promise of becoming yet more prodigious. So with regard to the application of science to the development of nature's powers, we are but in our infancy; and all that the united wisdom of man has yet effected, does not amount to a calculable portion of the infinite wisdom displayed in the smallest mechanism of nature, we can only go on, sifting, sorting, and selecting, by actual investigation, and close analogous reasoning, approximating

as it were all things living to something like a given scale of structure; but the mystery of mysteries cannot, ought not to be discovered, for if it could, man would cease to be what he is, and become coequal with his Divine Creator.

We will here take an opportunity of remarking that we do not affect to be able to throw many new lights upon this science, being ourselves but students, and the result of many years study of this branch of Natural History has only tended to render us more modest of our own abilities—more humble in suggesting an opinion sometimes adverse to that of our fellow-labourers in the same field, but, nevertheless, we feel it our duty to take advantage of their discoveries, and, by actual examination or analogous reasoning on our part, to verify the truth or point out the inaccuracies that have existed; indeed, were this not done, mankind would remain stationary in their knowledge, and the mind unexercised, would sink into a sickly state of apathetic feeling, inconsistent with its nature, disgraceful to its attributes in a higher order of enjoyment, that of looking up with reverential awe to God the author of all, confessing with humility that there is "good in every thing." In the different articles of malacology, under their alphabetical order, we have pointed out any discrepancies that our experience enabled us to verify, but we trust we have done so without that acrimony which unhappily but too frequently tinctures a difference of scientific opinion; and we honestly assert that, in so doing, it has not been from a spirit of self-conceit, or a wish to erect ourselves into censors of other men's understandings, but with a view of diffusing encouragement—a spirit of emulation, as far as in us lies, to the study of Natural History—smoothing the difficult path that leads to an acquirement of its principles—thus rendering it not only more in accordance with nature's laws, but more inviting to nature's admirers by its simplicity. Entertaining, too, a firmly-rooted conviction of its utility in promoting the great end of Christianity, and of its affording a never-ceasing source of worldly gratification, perfectly compatible with every man's more important duties of life in the relative stations of society. We have, indeed, in our times witnessed melancholy examples of miscalled philosophers, whose writings exhibit extraordinary proofs of mental powers, and the no less moral perversion of them: such are happily rare, and a certain antidote to the poison of infidelity can be always readily found by those who truly seek it:

"Each shell, each crawling insect, holds a rank,
Important in the plan of Him who framed
This scale of beings,—holds a rank, which lost,
Would break the chain, and leave behind a gap
Which nature's self would rue."—*Lepidoptera Britannica*.

Having in our article CONCHOLOGY promised to give some account of the system of Linnæus, compared with that now more generally, not to say universally, adopted, we cannot do otherwise than redeem our pledge, without however occupying our pages in the present place with an uninteresting detail of classes, orders, genera, and species, much better exhibited in a tabular point of view. It is also to be remarked that in every article relative to malacology, we have invariably mentioned the grounds upon which the Linnæan school must be abandoned in modern classification. We shall now, therefore, but very briefly state, that Linnæus, having formed

his system of conchology upon the forms of the shells with which the mollusca are most of them covered, without reference to the animals themselves, but very few molluscs, properly so called, of our time, were either examined or described by him. During the first nine editions of the works of Linnæus, he has not once mentioned molluscs, the animals now so designated being distributed, the naked species in his order *Zoophytes*, class *Vermes*, or worms, and such as were clothed with a shell, for the third order of the same class, under the denomination of *Testaceæ*. In the first he only distinguished the genera *Tethys*, with that he classed the *Holothurice*, *Limax*, and *Sepia*, which he placed close to the *Hydra*. In the second, which was not even at that time divided into univalves and bivalves, he characterised the genera *Patella*, *Cochlea*, in which were included all the turbinated univalve shells. *Cypræa*, *Haliotis*, and *Nautilus*, for all such as he afterwards called univalves, and under the name name of *Concha* he comprehended all the bivalves. He, nevertheless, also classed among his *Testaceæ* the *Ascidææ*, under the name of *Microcosmus*.

In the tenth edition of Linnæus, some augmentations were made, but the last during his life, the twelfth edition, the class *Vermes* are divided into five sections, in the second of which, under the denomination of mollusca, eight genera of true molluscs are described, *Ascidia*, *Limax*, *Aplysia*, *Doris*, *Tethys*, *Sepia*, *Clio*, and *Scyllæa*; the third is nearly all devoted to the *Testaceæ*, divided into multivalves, bivalves,

Conus generalis.

and univalves,—the first containing *Chiton*, *Lepas*, and *Pholas*; the second comprised fourteen—*Mya*, *Solen*, *Tellina*, *Cardium*, *Mactra*, *Donax*, *Venus*, *Spondylus*, *Chama*, *Arca*, *Ostrea*, *Anomia*, *Mytilus*, and *Pinna*; the third division, or that comprising the univalves, is subdivided into two, according as the spire of the shell was regular or irregular, acute or obtuse, as here figured in the *Conus* and *Bulla*. The genera

Bulla.

included were, *Argonauta*, *Nautilus*, *Conus*, *Cypræa*, *Bulla*, *Voluta*, *Buccinum*, *Strombus*, *Murex*, *Trochus*, *Turbo*, *Helix*, *Nerita*, *Haliotis*, *Patella*, and, by a remarkable singularity, the genus *Teredo*.

In characterising these genera, Linnæus merely al-

luded to some analogous naked molluscs, to which he imagined the shell must have belonged. If the more philosophical arrangement suggested by Adanson, with which he must have been acquainted, had any influence upon the changes this edition proves him to have made, it was but to a small extent, and that principally in the greater number of genera of shells, and a better description of the affinities of species; but the animal portion benefited but little, for we see among his mollusca the *Aphrodites*, *Terebellæ*, and the *Lernææ*, which are articulated animals, associated with the *Holothuria*, *Asteria*, and *Echinæ*, which are radiated animals. In the classification of his genera of *Tectacea*, the anomalies are far more numerous; we will not recapitulate them, as they will be found in the alphabetical distribution of this work. In short, every thing tends to prove that Linnæus was not properly impressed with a knowledge of the mollusca, or only deemed them an object of secondary consideration. With regard to conchology, Linnæus has created a nomenclature remarkable for its general accuracy and perspicuity; but, as we have had occasion to remark, in common with some of his greatest admirers, a language sometimes disgracefully offensive to modesty, and not to be sanctioned at any period in civilised society. It will be observed that the system of Linnæus has been as much assimilated as possible to malacology; his genera constantly preserved, though more naturally approximated, and the names of species, in many instances, not at all changed, though in this instance considerable reformation has taken place. With this slight outline of that portion of a system which will ever remain a monument of human industry and talent, combined with a rapid view of the changes which have taken place by the indefatigable researches and writings of more modern authors, we take leave of the article MALACOLOGY, once more repeating the impossibility of doing full justice to the subject or to its commentators in the space necessarily assigned us; we will, therefore, only take credit for having endeavoured to condense within our limits all that appears instructive, and, more particularly, indispensable to the student than to the scientific master, who, having already overcome the first difficulties, creates others for himself, resulting from the new light his understanding has received. Thus, no boundary can be fixed to knowledge: it were easier to circumscribe the current of the winds and tides than check its outspread: all that can be done is to turn it to useful purposes and a wise end.

It may be well to add here that a subtype has also been formed by the French naturalists, and called by De Blainville MALENTOZOARIA, or articulated mollusca. This group corresponds with the Linnæan system of multivalve worms, omitting the genera *Pholas* and *Teredo*, which are LAMELLIBRANCHIA. It contains two well distinguished classes, whose species are inhabitants of the seas of all countries, either fixed to submarine bodies, or possessing a free range. The first of these classes has evidently a considerable resemblance to the bivalve molluscs, as far as regards its calcareous envelope, in which, by examination, portions may be found analogous to those of the *Pholas*, and even to the tubular portions of other genera, which circumstance probably induced Linnæus to class that genera with those, as well as from the position of the head being downwards. There are also some resemblances, not to call them affinities, with the *Entomozoaria*, in consequence of their possessing horny-

articulated locomotive appendages, generally branchial at their base, becoming, towards the mouth, true denticulated cornuous jaws, upon which account they have been placed in this subtype as an intermediate passage to, or connecting link with, the *Entomozoaria*. The second class of this subtype has an evident connection, in many respects, with the *Cephalopods*; in fact, the animals possess the power of ranging freely and of climbing like them, and although no apparatus of special sensation has been discovered, the general configuration of their bodies is extremely analogous to that of the *Phyllidæ*, as there is, for example, a masticatory process, not very dissimilar to the *Patella*; but the most important difference may be remarked in the articulated disposition of the back of the protecting shell, and of the bundles or tufts of hair-like bristles; these, however, are each of them tubular, and doubtless acted upon by distinct muscles, as feelers or weapons of defence: the median termination of the intestinal canal resembles the animals of some of the *Chetopods* of the *Entomozoaria*, and, among others, the *Aphrodites*. Thus, it may be said, that the passage from the *Malacozoa* to the *Entomozoaria* is effected in two series from the *Acephalophora* to the *Heteropods* by means of the *Nematopods*, and the cephalous molluscs to the *Chetopods* by the *Chiton*, so that the two classes united in this subtype of molluscs are necessarily very different in themselves, but essentially conducive to illustrate the chain of natural gradation from this division to the next immediate one of nature, according to the position they now hold in the scale of creation. In the first class of the subtype, the first is that of NEMATOPODA, Cuvier, and Lamarck's CIRRHIPODA; it includes, first family,

Conia radiata.

Lepidacea, second family *Balanidea*, of which the *Conia radiata*, here figured, is an example. Second class POLYPLAXIPHORA, contains the genus *Chiton*—Lamarck's *Oscabrella* and *Chitonellus*.

MALACOPTERYGII—jointed fins. The second section into which Cuvier divides the true fishes, and which consists of three orders, the principal distinction of which is the arrangement of the ventral fins. The grand character of the division is that of having the rays of the fins jointed or composed of several pieces. Those fishes are very numerous, and comprise some of the most valuable genera, both of the fresh waters and of the sea. A list of them would be uninteresting as well as long; and therefore we must refer to them generally in their alphabetical order.

MALACOSTRACA (Leach). One of the primary divisions of *Crustacea*, having the shell or carapax of a hard calcareous nature, and comprising the crabs, lobsters, &c., forming the first subsection *Podophtalma*, with the eyes on foot-stalks; and the wood-lice, &c. (*Isopoda*, *Amphipoda*, &c.) forming the second subsection *Eriophtalma*, having the eyes sessile. See CRUSTACEA.

MALAY APPLE is the *Eugenia Malaccensis* of

Linneus, a fine ornamental tropical fruit-tree, cultivated in its native country. The flowers are icosandrous and the plant associates with the *Myrtaceæ*.

MALCOMIA (R. Brown), a genus of annuals, several of them very pretty ornaments of the flower garden. They belong to *Cruciferae*, and one species has been long known as the Virginia-stock seeds.

MALENTOZOARIA.—See **MALACOLOGY**, of which it forms the subtype.

MALLOW is the *Malva* of botanical authors; a genus of plants found in every quarter of the globe. The European species are mostly annuals. The South American are for the most part under shrubs; and the African, especially those found at the Cape of Good Hope, are evergreen shrubs. They are all easily increased.

MALPIGHIACEÆ. A natural order, containing above thirteen genera, and nearly four score species. They are all tropical, and consequently are kept in our stores in light loamy soil, and propagated by cuttings.

The genera included in this type, are small trees or shrubs, with apposite or alternate leaves, in general with stipules, and without dots or punctures. The inflorescence is axillary or terminal, solitary or aggregate, often racemose, the pedicles having bractes, and sometimes articulated, and the flowers regular and united.

The calyx five-sepaled, slightly connected by their claws, often glandular and persistent. Corolla is of five petals, which are free and inserted below the germen. The stamens are definite, seldom less than ten; the filaments free or connate; the anthers erect, roundish, two-celled, and opening lengthwise by chinks. The germen is formed of three united carpels, one or several celled; ovules solitary or pendulous, the styles distinct or connate, and the stigma beaded. The fruit is succulent or dry, three or one lobed and celled, the seeds solitary, with or without albumen.

Of the uses or properties of these plants, there is very little known; several have fragrant flowers, and the bark of some is bitter and astringent. The fruit of the Malpighia is eatable, and commonly known as the Barbadoes cherry. That of *M. glabra* is esteemed in the British West Indies and on the American continent. *M. saccharina* is the sugar plum of Sierra Leone, and is brought in great quantities to the market in Freetown; and *M. puniceifolia*, the bark of which is astringent, and the fruit when preserved delicious, yields a gum resembling gum-arabic. *M. urens*, *retosa*, and several other species, have leaves thickly armed with stinging hairs, like those of the *Macuna pruriens*, its fruit is insipid, but the bark is astringent.

The order contains the following genera:—Tribe 1. *Malpighia*, *Byrsonima*, *Bunchosia*, and *Galphimia*. Tribe 2. *Gertnera*, *Thryallis*, and *Ascarpa*. Tribe 3. *Hiera*, *Triopteris*, *Tetrapteris*, *Bannisteria*, *Heteropteris*, and *Vittmannia*.

MALTHINUS (Latreille). A genus of coleopterous insects, belonging to the family of *Telephoridae*, and distinguished by having the elytra shorter than the abdomen, and consequently not covering the wings when folded; the last joint of the palpi is ovoid. These are small active beetles frequenting flowers, and often of a pale colour, with yellow tips to the elytra. There are about a score British species.

MALVACEÆ. A natural order containing twenty-two genera, and above three hundred and ninety-one species. Some of the most splendid flowering plants

belong to this order, as the *Althæas*, the *Sidns*, and the *Hibiscuses*. Many are esculent and nutritive, and almost all are innocuous. The *Gossypium* which furnishes the cotton wool of commerce is found in this order, and many are medicinal as well as dietetic. They are herbs, shrubs, or trees, with alternate simple leaves, petiolate, stipulate, and for the most part covered with stellate down. The inflorescence is axillary or aggregate, and the flowers regular and united. The calyx is five-sepaled, supported by larger or smaller bractes; a torus surrounds the base of the germen, and bears both the petals and stamens. The petals are equal in number with the sepals, and are exerted alternately with them. The stamens are indefinite, filaments monadelphous, and the anthers one celled, kidney-shaped, and burst transversely. The germen is formed of several carpels set round the axes of the flower, more or less distinct, and one or many seeded. Styles equal in number to the carpels, distinct or united, and the stigmata variable.

Botanists arrange this order in two divisions. The first has the calyx double, and contains, *Malpe*, *Malva*, *Nuttallia*, *Ketelebia*, *Althæa*, *Lavatera*, *Malachra*, *Urena*, *Pavonia*, *Malva viscus*, *Lebretonia*, *Hibiscus*, *Thespesia*, *Gossypium*, *Redoutea*, and *Lopimia*. The second division has the calyx simple, and comprises, *Palavia*, *Cristaria*, *Anoda*, *Periptera*, *Sida*, and *Lagunea*.

MAMMALIA, (animals which suckle their young with milk, furnished by the *mammæ*, or teats, of the females). These constitute the most characteristic order in the animal kingdom, and have the system of sensation most perfectly developed. In common language they are termed quadrupeds, or four-footed animals, but this term is not correct, inasmuch as all birds, and many reptiles and fishes, have four extremities, analogous to those of the mammalia, though differing from them in various particulars, according to the modes of their action and the elements in which they live. Linneus was the first who applied the name mammalia as a general expression for them; and no name could have been more happily applied, inasmuch as it is common to the whole, and can be applied to no other animals whatever. It was long thought that the ornithorhynchus of New Holland, which has the mouth formed like the mandibles of a duck, and a single opening to the body as in birds, formed an exception to this general law; but more careful observation has shown that this animal suckles its young with milk, as well as the more characteristic mammalia.

All the mammalia have a double heart, with two ventricles for propelling the blood, on esystematic or propelling it over the whole body, and the other pulmonic, or sending it to the lungs; and they have also two auricles as appendages to the heart, one for receiving the blood from the lungs and transmitting it to the systematic ventricle, and the other for receiving the blood from the system generally, and transmitting it to the pulmonic ventricle. The blood of all is red and warm, but differs in its temperature in different species. It is aerated wholly in the lungs, and not partially by air cells or the coats of the arteries as in birds, and it is more minutely distributed over the system than in any other class of animals. They have also the nervous system, upon which, as we usually suppose, sensation and animal intelligence more immediately depend, much more developed than any other animals; and therefore, though there are great

differences among them, they are, taken altogether, much more intelligent, docile, and capable of training, than any of the other animals.

They are also the animals which are most useful to man; and, if the expression may be allowed, they are most kindred to him. They bear a part with him in his labour, their flesh supplies him with his best food, and their covering furnishes him with his warmest and most wholesome clothing. They also show attachments to man which are not shown by any other animals; and many of them have their affection unshaken by even very severe chastisement.

Mammalia are also more easily studied than any of the other classes of animals. They, generally speaking, are, like ourselves, inhabitants of the surface of the earth; for though a few live habitually in the water, a few others under ground, and a few others still make their way through the air by means of flying membranes, yet the characteristic locality of the whole mammalia is the surface of the ground. Generally speaking, too, they do not retreat into holes and hiding places, as is the case with most ground animals of other orders; they come out openly, and in the majority of instances, to the day, so that their manners are much more easily studied than those of any other animals.

The mammalia have accordingly attracted the attention of mankind in all ages. We find some of the most beautiful allusions to their habits in the writings of the prophets and poets of the Jews, which leave not the least doubt that, whether they had a regular system of the natural history of mammalia or not, they were well acquainted with the nature of the animals.

That the Greeks and Romans, and other civilised nations of antiquity, paid great attention to this department of nature there is no reason to doubt, though the fragments of their science which have been handed down to us are very imperfect, and in many instances ridiculous. We must not, however, blame them altogether for this; for the greater number of their works are lost, and of the few that remain the major part have been vitiated by the ignorance of transcribers. It was somewhat unfortunate for the science of the ancients that their language was an object of study in the middle ages, and at the first revival of learning, when the world was destitute of anything worthy the name of science. The consequence has been, that transcribers have greatly vitiated the works of the ancients, and they have vitiated none more than the works on natural history; for they have in many instances so blended together the fanciful allegory of the poet and the true story of the philosopher, that they have turned the whole into something approaching to the ridiculous. Notwithstanding the great learning, and the pure and commendable spirit with which the Sacred Volume was rendered into English, in which form it has probably communicated more real knowledge to the people of this country than all the other volumes that ever were written, it is to be feared that there was a sad deficiency on the subject of natural history, and that many of the animals as well as the plants which are called by names familiar to us, are not the same species which we call by those names. These, however, are matters which, though they must be regretted, cannot be repaired.

Among the ancients, the name of Apuleius stands high as an investigator of the animal kingdom, and of

the mammalia in particular; and it is reported of him, that he not only encouraged others to bring to him animals of all kinds, in order that he might study their structure, but that he himself made many long journeys for the same purpose. These works are lost, however, as are those of most of the earlier students of nature; and this is much to be regretted, because it is possible that some of those races of mammalia which are now extinct, and found only monumental in the dust, may have been living at the time when those ancients composed their treatises. Of the ancients whose labours are partially known to us, the foremost in respect to the mammalia are Aristotle the Greek and Pliny the Roman; the former a most acute thinker and original inquirer, and the second a very laborious but credulous compiler. When we think of the labours of Aristotle in the field of nature, we cannot help associating with his name that of Alexander of Macedon, who perhaps more truly deserves the name of "great" than any conqueror that ever drew sword. Trained under the Stagyræ, and deeply imbued with that love of knowledge and of nature, and that high tone of feeling which such a tutor was calculated to inspire, the Macedonian hero always sought to benefit as well as to conquer; and though other things are said of him, it is true that he lost his life by a marsh fever, when occupied in a careful investigation as to how the fens in the neighbourhood of Babylon might be drained, and the navigation of the Euphrates improved, so as to admit vessels of burden to his favourite city.

When, on the death of Philip, Alexander set out on his grand Asiatic expedition, his philosophic tutor declined the hardships of a camp, and preferred the philosophic ease of a residence at Athens. But under these circumstances the pupil and the preceptor did not forget each other; for there perhaps never was monarch so zealous in promoting science as Alexander. He employed, at an enormous expense, and in all parts of the world over which his sway or his influence extended, many thousands of persons, for the purpose of collecting animals and transmitting them to Aristotle, in order that that eminent philosopher might render his account of the living world as complete as possible. Every one knows of the severe penalty under which Alexander forbade his army to kill or even disturb the peacocks of India; and it is also pretty well known that our first tolerable account of the animals of that most abounding land was attained by him and his followers.

There is in the popular mind a strong prejudice against Aristotle; and in so far as his philosophy of the mind was concerned, this prejudice is well founded. But we must not blame Aristotle for this, we must blame those who blindly followed him when he ought not to have been followed, and made his philosophy occupy a place which, in the nature of things, it could not with justice occupy. Without revelation there could have been no proper system of intellectual philosophy, because the nature and the existence of mind are revealed truths; and therefore to set up Aristotle in Christian colleges was exactly the same kind of absurdity as it would be to set up the idols of the Greeks in Christian churches. But these matters have nothing to do with Aristotle as an observer and describer of nature; and in so far as these are concerned, to us unquestionably he is the father of the science, and as such entitled to our warmest gratitude. There is every reason to believe that as

they now appear, the works of Aristotle are really vitiated; because, while in one place they display the most cautious and scrutinising philosophy, where, to a less powerful mind, there might have been the most ample scope for romance, they in other places display abundant romance and absurdity upon subjects where it would not have required the genius of an Aristotle to see the truth. It is pretty evident, however, that the present order of his writings is not the original one in which they were given; and there is reason to suspect that many spurious passages have been interpolated both by ignorant and by designing transcribers, and also that much of the sterling matter has been lost in the course of time. These evils are no doubt much increased by the circumstance of Aristotle not being really the author of these works which have been handed down to us under his name. He was too much occupied in study for being an author; and thus he himself committed but little to writing; and accordingly, the works which bear his name were compiled after his death; in addition to which, they were subsequently mangled by a host of commentators.

Under all these disadvantages we must view the labours of this illustrious expounder of nature; and even then all that has come down to us is a mere fragment. He is understood to have composed fifty volumes or books on the history of animated nature; but of these only nine have been preserved. He lays down in his writings certain points of difference and resemblance observable among different animals, and then notices historically, and in detail, their general relations and characters. The sensible characters he deduces from the size, colour, and other external characteristics of the animal; from the number and position of its members, their dimensions, movements, and forms, with their comparative analogies or discrepancies; and illustrates his statements by numerous examples. His remarks also on their modes of life, their general economy, and various functions, seem to have been the result of the most accurate observation; and some of his positions which we once considered either fabulous or erroneous, have, on mature investigation, been found to be in perfect accordance with the phenomena of nature. He is believed to have been engaged in the dissection of animals, either with his own hands or by an assistant; and when the versatility of his talent, his unwearied diligence and research in acquiring an intimate knowledge of his subject in whole and in detail, is taken into account, it is not to be wondered at that many of his observations should stand the test of the strictest scrutiny, and that the student of natural history should still approach with reverence the relics of a system of which this great man may be said to have been the founder.

In point of eminence among the ancients, Pliny stands next to Aristotle; but he was a genius of very different character; for if Aristotle may be styled the father of inquiring and scrutinising naturalists, Pliny equally deserves the name of the father of compilers; and upon every branch of knowledge connected with nature, we are indebted to Pliny for a vast number of valuable observations, which otherwise would have been lost, so that one knows not whether most to admire the original acumen of Aristotle, or the second-hand laboriousness of Pliny. The variety and extent of his information is proved by the numerous host of authors whom he quotes; and he himself tells us

that his materials were extracted from two thousand volumes, which circumstance gives one some idea of the extent of his reading. The preface or dedication of his celebrated work addressed to Vespasian, though not altogether devoid of pedantry and conceit, exhibits every internal symptom of genuineness; but the first book, which consists of little else than a table of contents and authorities, is of a great deal more questionable authenticity. In one point of view the work may be considered as perfectly methodical. It begins with a general survey of the universe, embraces a geographical account of the terraqueous globe, of the history of man, of aquatic and terrestrial animals, of vegetables and minerals, of medicine and the arts, together with a vast variety of collateral and incidental subjects; and the entire production, even in some of its less interesting parts, is interspersed with anecdotes and philosophical reflections of at least a very pleasing character. It is true that large portions of the work can be considered only as compilations from the productions of others; but its general arrangement, as well as some of the details, together with its bold and nervous style, stamp the performance with an originality and dignity of execution. The style, however cannot be said to be either so pure or correct as it is bold and nervous. There is a striking combination of scepticism and credulity manifested on some occasions; but the marvellous stories recited by the author are generally founded on the testimonies of others; while those matters which have come within the scope of his own personal observation, are faithfully described, and there does not seem to be the least intention on his part to lead the reader astray. Some of Pliny's assertions also, which were formerly viewed as fabulous, have been corroborated by more recent observation and experience.

Oppian, in his poem of *Cynegeticon*, describes the manners, dispositions, and economy of many of the quadrupeds, which he introduces in lively colours; and though the nature of his work does not admit of anything like systematic observance of order in their classification, he shows an intimate acquaintance with the principle on which this ought to be based. He generally rejects those stories which are tinged with the marvellous, though a poet of a fanciful imagination.

Ælian wrote a treatise "On the Nature of Animals," consisting of seventeen books; but it is totally destitute of arrangement, and outrages every principle even of nomenclature and truth of description. Indeed, the only subject the writer seems to have had in view is, to exhibit the manners of animals with relation more or less aimed at the moral qualities of mankind; and with a few undeniable facts he mixes up a variety of fictitious matter. He however, takes care generally to quote the authority on which he gives these fictions; and is at some pains to impress upon the reader his own want of faith in them.

In the dark ages which followed the downfall of the Roman empire, and buried the human mind for a long time in the very depths of superstition, natural history was as much neglected as any other of the sciences. Among the most celebrated of its restorers, it would be injustice to pass over the name of Conrad Gesner, whom the celebrated Boerhaave styles "a monster of erudition;" naturally feeble in body, and rendered still more so by his experiments, the life of this illus-

trious man must have been a life of pain and sorrow. It was also a comparatively brief one, for he died, in the forty-ninth year of his age, a victim to the plague. But notwithstanding the painfulness and the brevity of his life, Conrad Gesner was one of the most extraordinary men whom the annals of the race contains ; and what he did under severe bodily sufferings and pecuniary privations, may serve to put to shame hundreds of pretended philosophers who dwell at ease, live in plenty, and repay the advantages which they enjoy by doing nothing. The feeble body of Gesner did not prevent him from exploring the Alps ; and though he was often obliged to write for his bread, he contrived to establish and support a botanical garden, and in addition to this, he was the first who established a regular museum of natural history. He contrived to collect a most valuable library, and amid all his difficulties to keep employed a painter and engraver to record his own personal discoveries. He may, in fact, be said to be the modern father of natural science ; for it was under him that natural history, degraded as it had been during the middle ages, rose to the rank of a department in philosophy. The works of Gesner are exceedingly voluminous, and would astonish many of the small authors of modern times, who deem the production of two or three little volumes an effort. Among the rest of his works there are four folio volumes on the history of animals, compilations in great part, but combined with a commentary, which shows that Gesner had made himself master of all that had been handed down from earlier times upon the subject ; and though his accounts are in many instances blended with fable, they are always amusing, and generally speaking instructive.

Gesner had a contemporary every way worthy of him in Aldrovando, who was Professor of Botany in the University of Bologna. This eminent man devoted his time and his talents, and expended his fortune, in the advancement of every department of natural science ; and he did so with a zeal and perseverance to which there is scarcely any parallel in the annals of philosophic investigation. He visited many countries for the express purpose of becoming acquainted with their natural productions, in order that he might describe them faithfully as they exist in nature ; and in order that the results of his labours might not be lost, he employed, for at least thirty years, some of the most eminent draughtsmen and engravers of Europe. His collections in natural history were most extensive, and laid the foundation of that museum of natural history which is still one of the chief attractions of the university of which he was so great an ornament. Though his classification is in many respects faulty, and his accounts of animals are often vitiated by fabulous and superstitious narrations, yet in general his descriptions of whatever came under his own notice are exceedingly correct ; which clearly proves that the errors and absurdities in his works are not faults of himself, but of the times in which he lived. His works, or at least the works which bear his name, amount in all to thirteen folio volumes ; but he is answerable for only six out of the thirteen, for the remaining seven were compiled from his manuscripts after his death. As is the case with Gesner, so Aldrovando was in a great measure a compiler ; and there is no doubt that both the one and the other, in many instances, sacrificed their own judgment to the absurd taste of the age. That taste

then ran strongly upon the implicit copying of ancient authorities, without inquiring as to whether the statements of those authorities were founded in reason or not. This fetter of the understanding was no doubt at first sacerdotal ; and the priests of an unreasoning and therefore unmeaning faith, finding that they had succeeded in chaining down the human mind in matters of religion, naturally laboured to do the same upon every subject in which thinking is concerned. This was the fatal moral and mental slavery of the middle ages ; and, for breaking the fetters of this slavery, the religionist and the philosopher are equally indebted to Luther and his illustrious compeers. It could hardly indeed be otherwise ; for those who, from the most worthless motives, stood between their fellow men and the revealed word of God could not fail to stand between them and the God of nature as exhibited in his works. Those times have, however, happily for the world, now gone by, and it behoves us to be tender of the errors and frailties of those who aided in breaking the fetters.

In noticing those by whom the knowledge of the mammalia has been promoted, it would be injustice to pass over the name of Johnston. He was a Polish physician, but travelled over most countries of Europe for the purpose of examining the animals which they contain, though the works which he has left recorded are in substance little else than abridgments of those of his predecessors.

At this period of the history of the science, we, however, come to a name which it is impossible for any lover of nature to pronounce without the highest veneration—the truly illustrious John Ray, the real father of natural history in Britain. Ray devoted fifty laborious years to the study of natural history, more especially zoology, and peculiarly the mammalia ; and whatever he touched was touched with the hand of a master. His Synopsis is the first regular and philosophical system that appeared ; and in proportion to the knowledge then attainable, we may perhaps say that it could not have been better. Ray was a thorough and searching philosopher, and at the same time a most admirable master of language ; so that his brief descriptions often contain more than the laboured and lengthened details of more modern authors. Ray too studied nature in the proper spirit, and of all the works which have appeared expressly upon the subject of natural theology, there is perhaps none equal in purity of spirit and depth of philosophy to Ray's "Wisdom of God in the Works of Creation." It is perfectly refreshing to revert to such a man, and we know not where the lamp of natural history can be so purely or so successfully kindled in the young, as at that unextinguishable radiance which this most illustrious of British naturalists has left behind him ; nor would it be fair to omit that Ray was as zealous for the civil and religious liberty of man as he was for the true knowledge of nature. He suffered, and suffered severely, under the mental bondage of a most illiberal and bigot reign ; and perhaps no expression of triumph is more sincere, and at the same time more touching, than that which John Ray expressed because he had lived to see the revolution in 1688 ; and what adds to its value is that it was as pure as fervent, for John Ray neither sought nor received, nor in all probability would have accepted any office of emolument, or any favour from any government upon earth, how much soever he might have admired its principles. It is one of the proudest

boasts both of England and of natural history, that John Ray was an Englishman and a naturalist.

Many minor names appeared in the interval ; but we can scarcely pause to notice any between Ray and Linnæus. This was a man of the most sterling merit ; and though his system is not exactly applicable in the present state of knowledge, it is unquestionably before the age in which it was written ; and though many parts of the writings of Linnæus are fanciful, and some of his names and classifications more poetic than natural, one cannot help admiring him as one of the most successful labourers in the field of natural history, and one whose very errors have been lights to show the truth, after those structural peculiarities of animals which were but ill known in his time had been illustrated by others.

Subsequent to Linnæus, we have to mention naturalists, or at least writers on natural history, of a very different class ; but yet who, though they perhaps did injury to zoology as a science, promoted the love of it among the people generally. At the head of this class we must place Buffon, whose fascinating volumes are so well known to most readers. That the style of those volumes is very inviting must be admitted, and the assistance which Buffon received from Daubenton, especially in the anatomy of the mammalia, gave considerable value to that part of the work ; but unfortunately Buffon was quite wild as a theorist, and, generally speaking, his speculations are of the most visionary nature, and even where his observations are valuable there are no means by which they can be generalised, so as to turn their value to account. Pennant was a most laborious observer, or at all events, describer ; but he brought to his work a deal of credulity, and freely gave to the world whatever he himself believed. Shaw, of the British Museum, was not much better, if indeed he was as good ; but his situation gave him various opportunities of being the first introducer of new subjects to the attention of the world, though he was loose in his nomenclature, and equally so in his descriptions. Goldsmith, and the rest of that class, who, though fascinating writers, must be acquitted of any general knowledge in natural history, may be passed over with little notice. That they promulgated much error and absurdity is perfectly true, but perhaps it is equally true that the charm of their writings has invited to the study of nature many persons who otherwise would have remained ignorant of it. In more recent times the science of zoology generally, and that of the mammalia in particular, have been more fortunate, because the structures of the animals have been studied at the same time with their manners ; and comparative anatomy and physiology have gone hand in hand with description, so that the functions of the different animals and the places which they hold in nature have been ascertained with a very great degree of precision. The establishment of zoological societies has contributed greatly to the promoting of correct knowledge with regard to the mammalia ; and perhaps there is no society which has done more service to the cause of science in this respect than the Zoological Society of London. Its committee of science is composed of some of the most accurate observers and the most skilful comparative anatomists and physiologists of the age ; and as their labours are carried on purely from love of science, and not with a view to any personal emolument or aggrandisement, they are the more meritorious.

In noticing the different labourers in this department of natural history, it would be unjust to pass over the late Baron Cuvier, one of the most eminent men perhaps that ever devoted himself to this or to any other science. Profoundly skilled in anatomy and in animal mechanics, Cuvier analysed the subject down to the ultimate principles ; so that while his arrangement of the mammalia is the most simple that ever was propounded, it is at the same time the most profound ; and though it would be injustice not to state that there are in Cuvier a few trifling errors in the details, the wonder is that his view of animals is at once so brief, so comprehensive, and so accurate. We shall not enter farther into the progress of the science of the mammalia, or the notice of those by whom that science has been promoted, for the names in these latter times would fill volumes ; and our object is merely to show the general interest which the subject has attracted in all ages. In order to be as brief and at the same time as perspicuous as possible, we shall arrange the few observations which we have to make on those interesting animals under different heads.

SECT. I.—GENERAL STRUCTURE OF MAMMALIA. Though, in one or other of their species, the mammalia are adapted to every locality on the globe, from the margin of the snows on the mountain top to the free range of the wide ocean ; and though in consequence of this there is necessarily a great diversity of structure among them, so that each may be fitted for its own locality in the best manner possible ; yet there is a general type which runs through the whole, and distinguishes them from all other animals. This type is not confined to the mere external shape of the animals ; for it runs through every part of them ; and the solids, the soft parts, and the coverings of the mammalia are all easily distinguishable from those of any other animal. This general type is, however, much more easily understood than described. It is difficult to give expression to it without falling into the description of some particular species, and by this means rendering it inapplicable to others. Still it is necessary that every one who pays any attention to those animals (and who does not pay attention to them ?) should have at least a general knowledge of their common structure, in order to judge of such individuals as may present themselves, and to perceive how finely their varied structures are adapted to their several habits in nature.

All the mammalia are symmetrical animals, divisible upon a mesial plane into two sections, which are the exact counterparts of each other, the one turned to the right hand and the other to the left. Some of the internal parts are not exactly divisible upon this plane, because these are soft, and often bent and convoluted, so as not to be divisible exactly upon any plane into symmetrical parts ; but all the external parts, and generally speaking all the solid parts, of the structure are thus divisible. If the part is single, the plane passes through the centre of it ; but if it is double, the two portions are situated at equal distances from the plane. It passes through the centre of the head, dividing the nose and mouth equally, and having an eye and an ear on each side of it. It passes through the centre of the spinal column in the back, and through the middle of the sternum or breast bone, and that of the abdomen on the opposite side ; or, as we say, speaking with reference to the general position of mammalia, the under side of the animal.

G 2

If the vertebral column terminates in a tail, which it does in most of the genera, though not in them all, the mesial plane also divides that to its very extremity. In walking animals, when on level ground the mesial plane is perpendicular to the horizon; and it is in this plane that the progressive motion of the walking and the swimming in mammalia is performed. If the foot is only a walking foot, and cannot lay hold or be brought to the mouth of the animal, or perform some other peculiar function, then the foot has comparatively little motion but that of being extended forward or drawn back in this mesial plane. Thus it is of importance to attend to this plane in the animal structure, because it presents us with the simplest view which we can have of the mechanical action of an animal. When we say "mechanical," we must not be understood as having the least intention to revive the old error of supposing that animals are machines; though the moving of any organ of an animal, and the progressive motion of an animal itself, are, when considered simply in themselves, purely mechanical; and we leave the mechanism of the matter behind us, and come to the essence of the animal, when we consider the impulse by which the organ or the whole animal is put in motion. With this explanation, the words "animal mechanics" may be used with the strictest propriety in describing both the general structures of animals and their adaptation to general habits, and the particular structures of organs and their adaptation to specific uses in the economy of the animal. In doing this, while we leave the subject of animal life—the unseen spring which puts the machine in motion—out of the question, the structure of the mammalia becomes one of the best studies that we have in practical mechanics; and though it is impossible to find out the precise use of every little peculiarity in the forms of the parts of animals, yet we always find, that when the animal is properly grown and in vigorous health, it exhibits a perfect model of mechanical economy. Every part of it is strong enough for the office it has to perform, and heavy enough for possessing the requisite stability in the performance of it, and this, not only in the ordinary circumstances of the animal's life, but also under a very considerable extent of contingency, so as to make it bear up against those changes in nature which appear necessary for the welfare of the whole system. But, at the same time, no strength is wasted, and no member is overloaded. The active principle of the animal has, therefore, in the organisation, the most extraordinary machine which we can imagine; and this machine is self-supported and self-moving, grows from an embryo by its own vital energy, and is capable of reproduction. Keeping out of view, in the mean time, the vital action of the animal, and also those instincts or impulses which stimulate it to the various external actions which it performs, we may say that the mechanical action of an animal in general consists in moving the weight of its own body, or of some part of it. Many animals, no doubt, do carry other things besides their own weight, in a state of nature as well as in a domestic state, but the natural cases of this are so few, and the fact itself blends so naturally with the consideration of the animal moving its own body or the parts of its own body, that this general action may be held as including the particular one.

Although, as we have already said, it is difficult, if not impossible, to form a general notion of the struc-

ture of the mammalia by referring to examples; yet when we consider that the moving of its own weight, or of itself and some supplemental weight, is the principal action of all the mammalia, and, with the exception of those which have flying membranes or swimming paws, all mammalia take their motions from the earth, or from some other solid, as a fulcrum of resistance, we have one step toward the adaptation of the whole structure of the animal to the performance of this action.

The motion of the animal must, of course, be either slower or quicker, taken in the general habit, which may in all cases be said to consist in seeking food, though there are many animals which move slowly when feeding, but which are yet capable of very swift and long continued motions; but when even this is the case, the animal has always some second purpose which is necessary for its subsistence or its safety. In many cases, the food of the mammalia, and especially that of those species which congregate in large herds, is seasonal in many places, and although mammalia cannot migrate over long distances and cross seas, as the birds can which make their passage through the air, yet there are many parts of the world where wild mammalia are under the necessity of making pretty long seasonal journeys, as is the case with the antelopes and other animals on the borders of the deserts, and, generally speaking, in all countries which, from periodical rains, are very fertile at one season of the year, but burned up with drought at another: all animals which are placid in nature are swift-footed, though when browsing on a good pasture their motions are comparatively slow.

Another necessity which animals of the same kind have for swift motion is, that they may be able to escape from their enemies. Many of them, when pushed to extremities, can defend themselves with great resolution, but still the general means of safety with them is flight; and the predatory mammalia, which are set over them in a state of nature to regulate their numbers, are all liars in wait, and not followers of their prey by swiftness of foot. The additional powers of motion with which mammalia are endowed for the purposes of migration and safety, are characters of the particular race however, and not of the general structure, so that we may consider slow motion and quick motion in the natural and usual mode of finding their food as two limits between which the simple and general motion of all mammalia may be considered to lie.

It must not, however, be supposed that the quick-moving animal performs more motion upon the whole than the slow-moving one; for it will generally be found that the continuance of the motion is inversely as the rapidity of it. The beast of prey, the lion or the tiger for instance, springs at once on its victim with the swiftness of an arrow, and it feeds ravenously, so that in a very short time its hunger is satisfied, and it lies down and dozes in a state of perfect inaction, until it is again aroused by hunger. The grazing animal, on the other hand, when it is on a bare pasture, grazes all day long, and proceeds constantly onward with a comparatively slow motion.

We might expect some difference, not merely in the structures but in the textures of animals, which vary thus much in their most general action, and we accordingly find that such is the case. The bones of the animal which makes the violent momentary rush upon its prey, and then reposes, are harder and heavier than those of the slow-moving animal. They

also bear; generally speaking, a less proportion to the quantity of flesh; and the flesh, including all the membranous and cellular tissues, as well as the muscular or fibrous parts, is much more hard and compact. The flesh, for instance, of an old ox, or an old sheep, which has been left nearly to nature in a suitable pasture, is tender and juicy, while that of an old lion is as tough as cables.

There are great gradations in this respect; and perhaps the instances which we have taken form nearly the extreme limits among the more characteristic mammalia; but we invariably find that as the animal approximates the typical one, which moves vigorously but briefly, there is a spareness and condensation in all the soft parts; and that in proportion as it approximates the opposite type, the soft parts become the more relaxed.

We find this exemplified in almost every species of domesticated animal, and man himself does not form an exception. There is no instance in which this is more remarkable than in the horse—an animal which is so obedient to breeding and training, that horses may be reared for almost any specific purpose to which such an animal can be applied, from the utmost speed of the racehorse, the more continued but less rapid motion of the hunter, to those unwieldy horses which appear to feel the burden of their own weight. It is not meant to be said that the whole character of the animal can be entirely changed to any single purpose, and thereby unfitted for every other, for no training can acquire so perfect a command as this over an animal; but still it is true that proper skill in the selection of the breed and in the training, can make the animal better adapted for some one particular purpose than for any other, and far better adapted for it than any other animal not trained in this particular manner. It is indeed this susceptibility of training, and consequent adaptation to a great number of purposes, which renders the horse so superior to all others as a working animal. The ass is stronger, more hardy, and more healthy; and the camel and the bullock can undergo fatigue under a load which no horse could endure; but when it has been said of these animals that they are efficient beasts of burden the tale of their whole history is told.

There are some of the elements wanting in order to perceive physiologically how those general changes in the animal system are brought about; and the chief one is our ignorance of the origin of animal motion. As we shall afterwards see, we can reduce it to a very simple fact, namely, that of the shortening and the thickening of a fibre; but though there have been many hypotheses upon the subject, we never can say why, or by what means, this shortening of the fibre takes place. We are certain, however, that it exhausts the animal in proportion to the rapidity with which it takes place, or in proportion to the quantity in a given time; but we have no means of estimating the strength of the original impulse in which this effort originates, because the impulse is not matter, and therefore we can only see its effect in the change which it produces on matter.

It is highly probable that this is a point upon which we shall never obtain any knowledge, and that we must content ourselves with the simple fact which we can observe; and this, though it is a little humbling to our pride, is of some advantage in pointing out the limits beyond which, if we attempt to use words, those words can have no meaning.

It is not necessary to point out particularly the more conspicuous external parts of the mammalia, for every one is familiar with them in some species, and, as we have said, there is a common type, or general resemblance that runs through the whole, but which admits of very considerable variety in all the individual parts. A head, a trunk, or body as it is usually called, and four extremities or limbs, are the chief parts; though in some species, especially those mammalia which swim, the posterior legs are united with the tail, forming a sort of fin; but this fin, even where most perfect, is never like the fin of a fish, any more than the membranes of bats and other flying mammalia resemble the wings of birds. When we consider those swimming and flying appendages of an animal of this class, we always consider them as departures from that which we take as the proper typical form of mammalia; and that, for example, though a whale lives in the sea, and is a most efficient swimmer in that element, yet that it is not the model of a sea animal, but a land one adapted to an aquatic habit. So also, though we find the bats in many instances incapable of motion upon the ground, while they fly readily, though heavily and in a flutter, yet we do not consider them as the characteristic inhabitants of the atmosphere, which range there with freedom, and buoyant and elegant flight. The owls have too many soft feathers in proportion to their weight for being graceful fliers; but still if a bat and owl are seen on flight at the same time, the flight of the owl is beyond all comparison more graceful than that of the bat, and the animal appears to be far more in its element.

We do not mean to say that it actually is so; for the whale in the sea, and the bat in the gloomy cave, are just as much at home and as beautifully adapted to their situations, as the wild deer on the mountain or the eagle in mid-air. We must, however, take some distinctions which are more general than those of single species, before we can get anything like an index to the facts of natural history, or to serve as an artificial memory to bring them to our recollection when they are necessary; and therefore we must take some one species, consider it as typical, and distinguish the rest according as they vary from this type.

This is a part of the subject upon which a good deal of caution is necessary, because the selecting of a particular type is our work, and not the work of nature; and whenever we mix our own work with nature's work, we always stand in jeopardy of laying too much stress upon our own, and giving it an importance to which it has no claim. We ought distinctly to bear in mind that our systems of arrangement are not knowledge, any more than words are thoughts; but the system and the words are alike necessary for the purposes of communicating; and it is our fault if we lose the substance in our vain attempts to catch the shadow.

It is not so necessary to mention this precaution in the case of animals generally, and in that of the mammalia in particular, as it is in the vegetable world; for the vegetable, rooted in the soil, must summer and winter in the same spot; and as whatever must naturally abide the blast is always tempered by nature to the blast, the vegetable is far more under the controul of external circumstances, and therefore subject to far greater variations of structure, than any animal, and more especially than the mammalia, which have much more acute sensation to warn them

of change, and many more resources in escaping from it than any other animals. Hence, it has chiefly been in the vegetable world that this yielding to circumstances in the individual plant has been verbally magnified into a sort of doctrine of transmutation, whereby, through the operation of a certain occult power which has been gratuitously conjured up, under the somewhat mystical name of development, roses may, in their initial state, be changed into thorns (meaning of course the spines on rose-trees); and, in certain more elementary states, that which might have been developed into a sea-plant, is developed into a land one, and the reverse.

It has also been maintained in the case of animals, that there is a progress from the very simplest; that from those which appear to have no distinct organs, and which can be readily propagated by dividing their bodies, up to the most perfectly organised animal, namely, the human body, there is a progressive development; and it is inferred, and sometimes in great part said, that, between the earliest rudimental embryo, and the full growth of the animal, or rather our first perception of it as an organised body, it must pass through all these successive developments. They do not of course fix the particular period of time during which the higher animal, as we may call it, is in the same condition as each of the lower ones through which it must come in the successive stages of its development. They do not, for instance, fix upon the precise minute at which a horse, which is afterwards trained to the turf, and wins the Derby or the Oaks, is a snail, a black-beetle, a tortoise, a penguin, or any thing else; neither do they actually aver that those developments take any measurable period of duration between the very earliest embryo and the final development of the specific animal; but there is a sort of dreaming belief upon the subject; and as dreams are said to occur only when the party is neither asleep nor awake, those philosophic dreams—or to speak more correctly, those dreams about philosophy—are more mischievous than one would be apt to suppose; for they will neither allow the error which they involve to slumber in oblivious repose, nor bring it so completely before the awakened mind, as that it can be detected and exploded.

This is not the way of dealing with nature; and though we cannot be too orderly in the arrangement of the facts of natural history, in that order in which the one shall most easily bring the other to our recollection, and where the connexion shall point where the new one is to be discovered, all system beyond the facts is mischievous; for it is an attempt to work without any materials. We can trace many of the mammalia up to a very rudimental state; and in that state it does not consist of so many organs visible to our observation, or is it composed of parts apparently differing so much from each other as these; but still whatever characters it has, are characters of its own species and not of any other; and as the progress of its development (we may with perfect propriety use this word when speaking of the evolution of an animal by the principle of animal life in itself, for this is identical with the animal); as this progress advances, we find invariably that the characters approximate more and more to those of the full-grown individual of the same species, unless under circumstances where we can at least understand how there may have been a deviation from the typical form, so that the individual may appear mutilated or monstrous; but it never

does, nor can we suppose it ever could, assume the characters of any other species.

This is not exactly the place at which to speak of deviations from the typical forms of species of mammalia; but we are to bear in mind that the young during the period of its growth has to work against the pressure of the atmosphere, and that of the parts by which it is surrounded; and also as there are no two individuals of any species absolutely alike, there must be differences of development in the different parts, arising from differences of strength and tone in the young vessels, of which we can have no very perfect knowledge. All this not only may be, but must be, and probably is so in the case of every individual animal, though the common cement is generally too early and obscure for us. This, however, is only part of that play of the system which prevails throughout the whole of nature, and without which, indeed, the operations of a working world could not be carried on. We shall not in the mean time, however, further prosecute this subject of diversity and occasional deformity in the individual animal with sufficient power to counteract the order of nature; but we shall briefly advert to those component parts of the structure which are common to all mammalia.

It is not our intention, because it is not necessary for the purpose of natural history, to enter into any minute chemical exposition of the substances of which the bodies of animals are composed. The elements, in the ultimate form to which they have been simply analysed, are carbon, oxygen, hydrogen, and nitrogen, with various alkalies and salts, and some slight quantities of metals. These are differently compounded in different tissues or textures of the body; but no connexion has been traced between the different chemical constitutions of the parts, and their different uses in the economy of the animal.

CELLULAR MEMBRANE may be considered as the fundamental structure of the bodies of all the mammalia; and that which holds all the other parts of the different organs together, whether their consistency be hard or soft. This, as its name imports, consists of a multitude of small cells united together; and it is found coating the most minute fibres of the muscles, as well as ramified through the whole substance of the bones; neither is there any vessel within the body of an animal which is not embedded in this membrane. Sometimes the cells are of considerable extent, and readily filled with foreign matter; as in the case of those surrounding and separating the muscles, and also in many of those in the internal parts of the body upon which fat accumulates; but those which surround the blood vessels are compact, with the cells nearly obliterated. It does not appear that this cellular membrane, or tissue, performs any distinct function in the animal, but is more in the character of a cement by which different parts are united together. Our next object, therefore, is shortly to notice the organs of motion.

These consist of two classes—movers, and substances immediately moved, though the moved substance very often carries the mover along with it. The movers, or active parts in the body which originate particular motions, and produce all the varied actions of animals, are muscles, to which there are various appendages, more numerous indeed in the structures of the mammalia than in those of any other class of animals. These are cartilages, tendons, and ligaments, which answer the purposes of

cords and other working tackle which connect the muscles with that which they move, or give direction and security to the motions.

The parts moved, and, generally speaking, the fulcra or points which give resistance so as to produce the motion, are the bones; and as they are the most permanent part of the animal, those which give stability and consistency to the whole, and which determine its general form and principal modes of action, it is desirable that they should be first understood; because the greater part of the action of an animal may be said to consist in moving or changing the positions of the bones. In doing this we shall first very shortly notice the general structure of bones and their appendages; and then take a very brief view of their number and arrangement in the human body; as that body, by not being adapted to any peculiar locality or kind of action, which is the case with the bodies of almost all other animals, is perhaps the best which can be used for this very general purpose. In treating of the bones and other parts of the animal structure which have no general English names, a few technical words are unavoidable; but we shall use them as sparingly as possible, and, generally speaking, accompany them by explanations, when such appear to be necessary.

BONES AND THEIR APPENDAGES.—Bones are very differently shaped, according to the purposes which they have to answer in the motions of the animal; and their shapes are often so peculiar, that to us they are unaccountable. But in every case where the complete use of the bone has been ascertained, it is invariably found that in shape, in strength, and in quantity of matter, the bone and also every individual part of it, are perfect, nor could an improvement be imagined by any device whatever. The bones of the limbs are nearly cylindrical, and they are comparatively straight, though those which are most loaded with muscles have generally a peculiar curvature, which both increases their strength, and makes the motions of the joints less jolting or jarring than it would be in the case of perfectly straight bones applied to each other. Others again are long and curved, as in the ribs; and bones of this form generally support the walls of cavities admitting of a varied capacity,—as the chest, which expands and contracts in the operation of breathing. Some bones are broad and flat, and when these have much fatigue to undergo, they are in general strengthened by a ridge placed longitudinally upon the external face of the flat bone. The blade-bones, which are embedded among the soft parts of the shoulders, and not articulated or jointed with the spine or back-bone, are of this description. The haunch bones which support the posterior part of the cavity of the body, forming a basin for this purpose, and also having the thigh bones, or first bones of the posterior extremities articulated to them, are irregular in their forms. Bones are also often elongated into a sort of branches at particular places; and those branches in general serve for giving a more extensive insertion to the muscles, and they also answer as levers in moving the bones from which they project. Those projecting branches, when they form a connecting part of the bone, are called processes, or *apophyses*, either of which words means that they proceed or project outward from the bone; but when they are less firmly united, and have the appearance of one bone applied to another, they are called *epiphyses*, which means that they have the appear-

ance of being applied or planted on the bone. For the sake of ready distinction, technical names have been given to these processes, according to the particular forms. When round and smooth, as they are in the extremities of bones which have a circular motion—as, for example, in the shoulder and hip joints of the human body—they are called heads; and they are received into sockets of greater or less depth; the head, when the bone is vertical, being always placed under the socket, in which position it is much less liable to be dislocated than if the position were reversed. When the motion of the joint is in one direction only, with comparatively little lateral play, the extremity is called a condyle; and it is a portion of a greater or smaller circle fitting into a concavity which is sometimes single and sometimes double, thus forming a hinge. The working extremities of bones at their articulations are often, however, far more complicated than this, and by means of variously shaped bones, and the sliding and rolling motions thence produced, a degree of play, still consistent with perfect firmness, is given to the limb of the animal, which it is altogether impossible to imitate in common mechanics. The human hand and wrist, and indeed the whole bones of the arm, and the mode of their combination, furnish one of the most remarkable instances of this, as we shall afterwards have occasion to notice at greater length.

Of the permanent processes to the extremities of which other bones are not always united by articulation, the following are the principal names and distinctions:—*Mastoid*, or those which have some fancied resemblance to a nipple; *Coracoid*, or those which are something shaped like the bill of a crow; *Styloid*, or those which resemble the style or bodkin used by the ancients in writing; *Spinous*, or those which stand out like a thorn; *Pterygoid*, or those which are supposed to be something like a wing; and *Zygomatic*, or those which have some resemblance to a yoke. When the irregularities on the bone merely roughen the surface with roundish projections, they are called tuberosities. These names are, of course, merely conventional; but as they are used by every writer who treats of the forms of the bones, and the motions of which they admit, with any thing like precision, it becomes necessary to know them if we are to study the structure or the living action of animals with any thing like the proper advantages. Bones are never, or at least seldom, in the mammalia of the same consistency throughout their whole section when divided. The long cylindrical bones have generally a hollow in the middle part which contains marrow or fatty matter in the full-grown animal, but has more of the colour of blood in the young subject. Toward their extremities they become cellular, the cells being still filled with fatty matter, and at these parts the central cavity is gradually obliterated. There are also usually openings into the bone for the admission of vessels; and there are also frequently grooves along their surfaces. The thin bones consist of two plates, which are called tables, with a spongy diaphyse between them.

In the working structures of the body, bone never touches bone, and therefore we must attend to the basis of bones, as it were, in seeking to know something about its nature. In the middle part of the bone this basis is composed chiefly of gelatine or animal glue, which boils soft, and may be extracted from the bone by boiling for a sufficient length of time;

but the working ends are covered with cartilage of a bluish-white colour, and very elastic; this differs in its chemical nature from the basis of the rest of the bone, for it contains a good deal of albumen; and it is worthy of remark, that there should be this difference between the mere cement which retains the earthy matter, whereby strength is given to the bone, and that which enables the extremity of one bone to work smoothly on another. There is an oil provided by nature for all those working extremities, but they are themselves also very smooth, and composed of matter which is very elastic, so that they are but little liable to jolt, which, in the more violent motions of animals, would shatter the bones to pieces. No doubt the way in which the different bones come into action contributes a great deal to this purpose, for it never strains directly upon the end of a bone, nor yet on the side of it, so that one bone supports another. By this means, a blow given with the extremity of the limb is capable of breaking a substance stronger than any part of the limb itself.

The cartilaginous basis of the bone is an elastic or flexible substance, as well as that which covers the moving parts; and it does not appear that any truly animal formation, while it is in the living state, can acquire such hardness as to be stiff and inflexible. It is reasonable to suppose that this should be the case, because living matter is in a state of continual change, by the old being taken up and new deposited in its place, and it does not appear how this could be done in an inflexible solid. Hence the bones are rendered stiff by the accumulation of a quantity of earthy matter in the cells or interstices of the cartilaginous bases. Those earthy matters are all salts of lime, the same as they exist in minerals, or any where else, without any reference to their being products of animal life; and therefore, though they are unquestionably deposited in the bones by the action of the animal, they cannot in themselves be regarded as animal matter—that is, matter which it would be vain to seek for any where save in the structure of an animal. They consist chiefly of phosphate of lime, carbonate of lime, and sulphate of lime, of which the first predominates in all bones except the enamel of the teeth. It is less dense than the other salts of lime, and not so brittle.

How these salts of lime come to be deposited, we can no more tell than we can tell why any animal is of one specific form and not of another. We are certain, however, that it does not exist in the very early stages of life, because there is no earthy matter in the bones then; and, though we know not the process, we can observe the progress of its formation. The process is called ossification, which means changing to bone; and it appears to be an operation of the bone itself, for it always takes place in the middle, and proceeds gradually from a series of points, until the whole bone is ossified. It appears, also, that this complete ossification limits the growth of the bone, and that before it is absolutely completed the stature of the animal ceases to increase. It appears, also, to be the part of the animal system which, in the gradual decay of nature, and without any local injury or casualty of disease, is the first to give way. We seldom see wild animals in a state of decrepitude; because, depending wholly on their animal resources, they are more liable to contingencies than human beings; but we readily perceive, in the decay of the human subject, a remarkable exhaustion of the bones before the structures which are more immediately concerned in

the functions of life begin to give way. Their limbs become feeble and tottering, their vertebral columns bent; and they seem gradually to sink towards that grave which is the place of final repose for every animal body. In these cases it is evident that some contraction takes place in the bones; they are dried of their juices, and there is reason to believe that either their salts of lime are taken up by the absorbents, or the materials necessary for their formation are retained in the larger vessels, and precipitated on their coats, forming what are usually termed ossified vessels.

Besides the cartilaginous base and the salts of lime, which give stiffness, every bone is covered externally by a firm membrane, the periosteum, which means that which is round the bones. This membrane does not extend to the working surfaces of the bones, or those which are covered with cartilage; it reaches nearly as far as the parts which are actually bone. It is exceedingly sensitive; and it becomes indurated in its substance as the animal waxes older. In the young animal, its connexion with the bone is but loose, but as the animal advances in age it adheres more and more firmly. It appears to be essential to the healthy state of bone, for if the periosteum is destroyed from any part, the surface of the bone scales off or exfoliates; and if the periosteum becomes diseased, it speedily eats into the substance of the bone, and destroys its texture. Such are the leading particulars of the supporting structure of the mammalia, in so far as the substance, growth, and decay of that structure are concerned; and we shall now advert to the arrangement of the bones in the human skeleton, to which we can afterwards refer as a standard, in order to show how the divarications from this standard, which we find in the other animals, are essential to their more confined and localised species of action. In the human skeleton—skeleton is the name of the entire bony structure of an animal, and is peculiar to vertebrated animals,—in the human skeleton, as in all the others, the vertebral column, or spine, is the foundation upon which the whole skeleton is organised; and, indeed, as vertebrated animals are the only ones in which the system of sensation, the characteristic animal system, is fully developed, it may be said that the whole structure of the animal is founded upon this column and its contents. One extremity of this column supports the head, and the other extremity is supported by the feet, through the medium of the bones of the pelvis or lower cavity. The bones themselves are so many, that it is necessary to classify them so as to remember the groups, and then each group becomes a sort of index to the individual bones of which it is composed.

The first and most obvious division is into the head, the trunk, and the extremities; and this division applies to the whole class of mammalia. The bones of the head admit of subdivision into those of the cranium and those of the face; the former enclosing and defending the brain, which is understood to be the most important organ of a sentient animal; and the bones of the face supporting the mouth and those organs of sense which are directed to the front. The cranium consists of eight bones, and the face of fifteen, besides the thirty-two teeth, which do not come properly within the class of ordinary bones.

If we include these in the number, and also the peculiar bone of the tongue, and the small bones in the apparatus of the ear, the total number is sixty-three.

The trunk also admits of subdivision into the vertebral column in the middle of the back, the sternum opposite to it on the breast, the ribs in the sides, and the *ossa innominata*, or unnamed bones, which form the basin of the pelvis. The vertebral column consists of twenty-six pieces jointed together, and admitting of a vast number of flexures, but not of any great motion in a single joint, excepting in one or two, which we shall mention afterwards. Of these vertebræ, or jointed pieces, seven belong to the neck, and are called *cervical vertebræ*; and this number seven is common to all mammalia, whether the neck be long or short. In some of the cetaceous mammalia those vertebræ are so exceedingly short, that the neck appears to consist of thin plates of bone, which have scarcely any motion; while in some other animals, as in the giraffes for instance, it is exceedingly long, but this is owing to the greater lengths of the vertebræ, and not to any increase in their number. The next part of the column consists of twelve joints, of the back or dorsal vertebræ as they are called, which have less motion upon each other than any of the rest. Then there come five joints of the loins, or *lumbar vertebræ*, after which there are two terminating bones, the *sacrum* and the *coccyx*. The breast-bone generally consists of three pieces; but these are often so united as to appear only one bone. The ribs are twelve on each side, of which the seven which are nearest the head are called true ribs, and the five towards the loins false ribs; the former are joined both to the processes of the spine and to the sternum, though these are not articulated so as to have one surface moving upon another in either case; but the union is formed by flexible cartilage, and the ribs, both true and false, are capable of a limited degree of motion. Properly speaking, the pelvis consists of only two bones, one on each side; but each is divided into three parts—the hip-bone, the haunch-bone, and the share-bone. Thus the number of bones of the trunk varies, according to the view which we take of those bones of the pelvis and the breast-bone. If we count each of these only as single, then there are fifty-three bones in the trunk; but if we consider them as divided, then there are fifty-nine.

All the bones that we have now enumerated, and indeed all the bones in the body, are perfectly symmetrical, whether they exist in pairs, with an entire bone on each side, or whether they are single bones equally divisible in the mesial plane.

The anterior extremities, which are the arms in man and the fore legs in the other mammalia, consist of thirty-two bones each, and the posterior extremities consist of thirty, which gives sixty-four in the pair of the former, and sixty in that of the latter. It is convenient for the sake of brevity to call the anterior extremity the arm, and the posterior the leg; and if this is understood to refer to the mere position of the extremity, and not to the function which it is best fitted for performing, it can occasion no mistake, though applied to all mammalia whatever. There is even an advantage in this general nomenclature, because it lessens the number of mere names, and by necessary consequence increases that of descriptions; and it also enables us more readily and clearly to see the differences of structure in those parts of animals, and to understand and appreciate those differences of action, which result from, or are dependent upon, the differences of structure.

The bones of the arm consist of two uniting bones, the one of which is the blade-bone, embedded in the flesh of the back, and joined to the other parts of the skeleton, the ribs chiefly, only by muscles; and the other is the clavicle or collar bone, which extends from the top of the shoulder to the upper part of the sternum, the latter union being made by means of flexible cartilage; and thus this bone admits of considerable motion in that part of the blade-bone which contains the cavity for receiving the upper part or head of the humerus, or bone of the arm above the elbow. There is only one bone in this part of the arm, and it is the same in the corresponding part of the leg; and this runs through the whole of the mammalia. The fore arm, from the elbow to the wrist, consists of two bones; the wrist, (*carpus*), of eight bones; the palm of the hand (*metacarpus*) consists of five bones; the fingers, of three bones each; and the thumb of two bones. The bones of the fingers are called phalanges, because they are ranged something like a line of warriors in a battle phalanx, when viewed across the hand; and when we take them in succession they appear rank after rank.

As the head of the femur or thigh-bone is articulated immediately on the bones of the pelvis, it does not require that support which the arm gets from the blade-bone on the shoulder, and the collar-bone on the upper part of the breast; but the consequence is, that without flexure of the whole body, the point to which the leg is articulated has not so much motion of its own as that to which the arm is attached. This, however, is a great advantage in the use of the leg, and gives it a stability which it could not have possessed if the point to which it is attached had been moveable as the shoulder is; and on the other hand, the arm would not have been applicable to very many of those purposes which it can perform well, if the point of its insertion had not been movable, without the whole body being moved along with it. There is not such complete difference between the mobility of the point of attachment of the arm, and the firmness of that of the leg, in any animal, that there is in man; and this is the reason, or at least one of the chief reasons, why man walks so much better in an erect position than any other animal, and also why man can use his hands in so many different positions, while the body remains perfectly steady, though resting on only the part of one foot.

This is a part of the subject to which the greatest attention should be paid by every one who wishes to understand the action of animals, and why one animal and not another is found inhabiting a particular place, and performing particular operations; for it is according as the arm or the leg, or both, deviate from this type at their primary articulation, that we find them diversified throughout the greater part of their length. If the arm become principally a leg—that is, if it is used for scarcely any other purpose than that of walking—the blade-bone is comparatively loose upon the shoulder, and the collar-bone is wanting or imperfect; on the other hand, if the leg partakes of the character of an arm, and is furnished with a hand, or more correctly speaking a prehensile foot, it is invariably loosened in the joints, has a wriggling lateral motion, and is comparatively unfit for the proper function of a leg. We shall be better able to explain this matter, however, when we come to compare the other orders of mammalia with man as this typical animal. The number and arrangement of

the bones in the human leg are as follows:—one in the thigh as already mentioned; one on the knee, the knee pan, which is embedded in the tendons, and serves to keep the joint steady, and also to protect those tendons from injury when the knee is very much bent, and to prevent it from bending in the contrary direction, and yet leave it more flexible than it would be if its motion were stopped by bone, and fatigue it less than if it were held back merely by soft matter. After these, the leg itself contains two bones; the tarsus, or ankle and heel taken together, consists of seven bones; the metatarsus, of the same number as the metacarpus; and the toes, also of the same number as the fingers and the thumb, the great toe having only two phalanges as the thumb has, and each of the smaller toes three. Thus the whole skeleton may be said to contain two hundred and forty bones, besides those which, as we have remarked, may be regarded as made up of, or divided into parts.

We shall now introduce a figure of the skeleton,

and proceed to make such general remarks upon it as may prepare us for understanding how the different bones are united together in their natural arrangement, and in what manner they are worked by the muscles; and this comprises the whole mechanics of the body, and furnishes us with a standard whereby to estimate the general mechanics of the mammalia.

We shall glance very briefly at the bones composing the several parts in their order; and though our figure is a mere sketch or simple index, and we have not confused it by references, yet any one may, by means of it, and his own body, easily make out the positions and general forms of the principal bones, which is at all events a beginning.

Bones of the Head.—The frontal bone, which is a

very characteristic one in the human subject, forms the forepart of the skull, and the upper arches of the orbits of the eyes. It has various elevations on its external surface, is perforated in its substance by the frontal sinuses, and has some spinous processes on the inner surface, which serve to keep the brain steady in its cavity. The ridges and inequalities on this, and on all the bones, are far more conspicuous in the male subject than in the female.

The parietal bones, or walls of the skull, compose the upper part behind the frontal and the sides; and they have not any very remarkable projections from their surfaces, neither are they perforated for the admission of any important organ; but there is a hole in each, near the corner at which it joins the frontal bone and the temporals.

The temporal bones form the lower parts of the sides of the head, and may be said to contain chiefly the organs of hearing. They also have various processes on their surface, and are pierced with holes for the passage of arteries and veins.

The occipital bone forms the back of the head, and it is the bone by means of which the head is articulated on the spinal column, and also that through which the spinal continuation of the brain finds its passage into the tube or cavity which all the vertebræ contain for its reception. The joint here is a hinge joint, having the plane of its action parallel to the mesial plane. It is double, there being two condyles, or knobs on the lower part of the bone of the skull, and two cavities in the upper side of the vertebræ, on which they work. This gives protection to the spinal marrow, and also allows the head a very considerable range for motion backwards and forwards; but this is not the joint upon which the lateral and twisting motions of the head are performed. This is the joint, however, that gives the principal motion to the head in the direction of the mesial plane, and the one upon which the head is balanced; and so well is it adapted to the keeping of the balance, that the condyles of the occipital bone are, on the average, immediately below the centre of gravity of the skull and its contents.

The sphenoid, or wedge-shaped bone, forms the base of the skull. It has many processes and irregularities on its internal surface, by means of which it keeps the brain upon a very firm base. It is perforated by the two openings by which the eyes are connected with the internal cavity of the skull.

The ethmoid bone is situated at the back of the nose, and unites the proper bones of the nose to the frontal bone. The bony plate of the nose stands out from it; and its cavities, from which it gets its name, which means that it is like a sieve, are the chief receptacles of the organs of smell. The frontal bones of the nose are the nasal bones, which form the firm part at its union with the frontal bone; and they are pierced so as to admit the matter of tears generally into the cavity of the nose, though these last are, more strictly speaking, bones external of the nose, or rather between it and the inner parts of the orbits of the eyes. They are the ungual bones.

The cheek bones are situated below the eyes and support the cheeks. They have various processes and cavities, and their form gives considerable character to the head.

The upper jaw bones contain the sockets of the upper teeth, and also form a considerable portion of the palate, and serve to continue the organs of smell

to the mouth, where there is so curious a sympathy between them and the organs of smelling. The bones of the palate, properly so called, are situated in the hind part of the palate, and between the cavity of the mouth and the nasal openings.

The vomer, or ploughshare bone, stands out from the ethmoid, and forms the principal part of the septum, or partition which separates the nostrils from each other; and this is prolonged in the cartilaginous part of the septum, as the sides of the cavity are by their cartilages.

Nose of the bones that have hitherto been mentioned have any proper articulations upon each other. They support the brain, and the principal organs of the senses, as well as afford the plane of resistance against which the lower jaw acts in preparing the food for the stomach, and they also give assistance to the muscles which move the jaws and the eyes, and give all the varied expressions to the face; but none of these can be said to be subject to any of the mechanical actions of the animal. The other principal bone of the head is different. That is,

The lower jaw, which has both a vertical or opening and shutting motion, and a lateral rolling or grinding one; and all mammalia which have this last motion of the lower jaw, are capable, in part at least, of subsisting upon vegetable food, whereas there is no such motion in animals which kill and eat other animals.

The teeth, when complete, are thirty-two, eight in each side of each jaw. Eight of these are incisors, four canines, and the remainder grinders, equally distributed in both jaws. The incisors have only one cutting edge, and a single fang or root; but the grinders have double flattened crowns, and each of them has two roots. They are not, however, so decidedly grinding teeth as those of the animals which feed solely upon vegetable matter. In these, the enamel, or harder part, is dispersed in ridges or layers, alternating with the bone; but in the human grinders the enamel covers the whole crown of the tooth.

We shall mention some of the leading forms both of the partial and the more complete motion of one bone upon another, when we come to treat of those parts of the skeleton in which such articulations occur; but as the bones of the head form one of the best instances of the union in which there is no motion, it may be proper to notice them here.

The general technical name given to this kind of union between bones is *synarthrosis*, which implies that they are equally related in the junction, or that neither of them moves upon the other. The union, or line of union, is called a suture or seam; and it is distinguished as serrated, or toothed when the bones are indented into each other. This is by far the firmest kind of suture, and we accordingly find it at the union of the most important bones—the frontal, parietal, and occipital bones of the skull, and the cheek bones. This kind of suture is very difficult either to be separated or displaced. The second kind of suture is that in which the edges of the bones are merely brought together, without any toothing or interlocking. This is a feeble kind of union, as compared with the former, and therefore it occurs between such bones as those of the nose and the two parts of the upper jaw, upon the union of which there is little strain. The third kind is called squamous or scaly, because the edge of the one bone is thin and overlaps that of the other. The temporal bones form this

sort of suture with the occipital, which they overlap at the junction. From its form, this suture is more yielding to a strain than the others are.

All the three forms, however, yield more than if they were a solid bone, and when a fracture of the bone does happen, it is not propagated beyond the suture. All these contrivances render the skull much stronger with the same quantity of materials, than it could have been rendered by any other means; and as in man the upright position supports it nearly upon the centre of gravity, it is borne in the easiest possible manner upon a column, which is so finely adapted for supporting it.

Bones of the Trunk.—As the skull is the chief bone of the head, and contains the brain, so the spine is the most important bone in the trunk, and contains the continuation of the same mass. The spine, in the balancing of the body in all the varied attitudes which are necessary in the human subject, requires to be firm, and at the same time flexible to a considerable extent; and as injuries to the contents of this spine are of the most fatal nature, it is necessary that, in all its motions, it should be protected against dislocation. This is accomplished by the numerous processes with which the vertebræ are beset, and by the mode of their union, and the nature of the substance that unites them. The processes of the spine are so arranged, that it is not very easy to dislocate a spine without breaking some part of it. The muscles which give it its motions have comparatively little or no power upon the joints, and the matter with which these are connected is very tough and elastic. All the different parts of it have different kinds of motion. In the neck, the lateral motion across the mesial plane is nearly as great as that in the plane; but in the dorsal vertebræ, where the ribs are attached, and where their order would be deranged, and the contents of the chest disturbed by a great extent of lateral flexure, the cross motion is more limited. There is a contrary flexure in the spine, which is at once graceful and contributes to the strength of the organ. The upper extremity inclines forward, so as to reach the central part of the bone of the skull, and this at the same time affords room for those muscles and their tendons, which communicate the principal motions to the head. The spinous processes in the upper part are short; and it is not till we come to the setting on of the neck, as it is usually called, that we can feel a prominent process through the skin. They are more produced in the dorsal vertebræ, and they are far more produced in running mammalia, which require a firmer lateral support to their blade-bones than is necessary in man.

The projecting parts of the vertebræ of the spine, and their perforations may be briefly stated as follows:—The first vertebra of the neck, which immediately supports the condyles of the occipital bone has two transverse processes, two articulating ones, and two inferior oblique ones. This vertebra is styled the *atlas*. The second vertebra is called toothed (*dentalis*). It has two transverse and four oblique processes; and the articulation is a cleft tooth-like process, which acts in the cavity of the atlas, and admits of the lateral and twisting motions of the head. The remaining five of the neck resemble the second one in other respects; but they have not the toothed process. All these have the central opening for the spinal marrow, and two lateral holes in each.

The vertebræ of the back and loins have the same

number of transverse and oblique processes as the last five of the neck ; but those of the back have long pointed spinous processes, and those of the lower have processes of the same kind, but shorter and blunted. The spinous processes give the spine a firm embedment in the muscles; the lateral ones have the ribs soldered to their inner surfaces, with the head of the rib resting on the thick or articulated part of the vertebræ; and the oblique processes are the principal means by which dislocation is prevented. In proportion as the column has more weight to carry, and is less supported by the muscles and ribs, its diameter, and also the articulating surfaces of the vertebræ are enlarged. All these have the cavity for the spinal marrow; but they have no lateral holes.

The sacrum, which is again deeply imbedded in muscles, has three spinous processes, but no oblique ones; within it the spinal marrow terminates in a triangular cavity. It affords support to the spine; and it is also the centre of the bones of the pelvis. The coccyx is a simple bone attached to the termination of the sacrum, having no spine or internal cavity; and its chief purpose is to afford support to the terminal part of the intestinal canal.

The bones of the pelvis we have already mentioned. They are connected with the sacrum at those portions which are called the haunch bones (*ilii*); on the sides are the hip bones; and the share bones advance in front completing the cavity. The haunch bones have two tuberosus spines, and the share bones or bones of the pubis, form an arch; and in the hip bones on each side there is situated the cavity (*acetabulum*), which receives the condyle or head of the femur or thigh-bone, which is the principal articulation of the leg. These bones altogether support the lower parts of the viscera, and also the base of the spinal column; but from the intervention of two unions of separate bones on each side, between the insertion of the femur and the spinal column, any shock or concussion which is communicated to the hip-bone by rapid motion of the legs, is not propagated so as to jolt the contents of the spine, or to disturb the viscera contained in the pelvis. The form of the bones of the pelvis throws the articulations of the femoral bone proportionally farther apart from each other in man than they are in the other mammalia. In the male subject this distance may be considered as the one which conduces most to give the trunk a stable base. Physiological causes render it necessary that this measure should be rather exceeded in the female; and this is compensated by a slight inclination to each other of the thigh-bones at their distal, or knee ends, which gives a peculiarity to the walk of females different from that of males.

The remaining bones of the trunk are the sternum and ribs. The sternum, or breast-bone, is flattened; and though they are intimately connected, it consists of three bones, by which means its flexibility is much increased, and the danger of fracture diminished. At the under end it terminates, or is sheathed by the *ensiform*, or sword-shaped cartilage, which answers in flexibility to the false ribs which form the lateral walls of the lower part of the chest; and their sternal extremities are united by the cartilage. The sternum contains cavities to which the ribs are articulated; but, as we have already mentioned, their opposite extremities are merely soldered to the lateral processes of the vertebræ, so that though the sternum

and ribs are much more flexible than any other of the assemblages of bone, and therefore a strain or thrust is much less readily propagated through them to their union with the spine; yet provision is made against the possibility of jarring the spine even in this way. We cannot, indeed, whatever part of the skeleton we advert to, avoid noticing the universal and admirable provision which is made for preserving this organ from the effects of any of those violent actions to which the other and less essentially vital parts are necessarily often subjected in the exercise of the body. There is no bone articulated directly upon any part of the spine, but the unions are formed by flexible matter, consisting partly of cartilage and partly of elastic ligament; and thus the brain and its continuation are everywhere supported upon springs, springs of a far more delicate nature than those which we construct in our mechanics. When the pressure is great upon the spring, that spring is doubled; and on the other hand, when the motion of the bone approaching the spine is extensive and varied, as it is in the blade-bone, there is an embedment of muscles and of cellular membrane between the moving bone and even the ribs.

The seven true ribs on each side, extend from the dorsal vertebræ to the sternum, having heads and tuberos processes at their dorsal extremity, being united to the sternum in front, and each being furnished with a groove, along which an artery is conducted. The five false ribs are connected to the transverse processes of the lumbar vertebræ; but at their anterior extremities they are united by cartilage one with another; and the first one with the last of the true ribs. As this cavity of the body contains the most active portion of the respiratory and circulating systems, it is necessary that it should have the power of contracting and enlarging with very little effort; so that the pressure upon all the delicate organs and vessels which it contains may be uniform; and yet that the requisite quantity of air in breathing should be alternately received into the lungs and discharged from them. Nothing can be more yielding to internal pressure; nothing better adapted for resuming its shape when that pressure is removed; and nothing equally light in its structure can be stronger or more secure against external injuries than the chest.

Bones of the arms.—In considering these, the first thing to be attended to is the point of insertion; because that, in a great measure, determines the principal action of the articulated members. The blade-bone and the clavicle are the two supporting bones in the human subject. The blade-bone, as already mentioned, is embedded in the muscles of the shoulder, and it is itself the point of insertion, or rather the surface of attachment. It is formed with three ribs, a dorsal spine, and three processes, against one of which the clavicle or collar-bone abuts; and the others support the muscles and prevent dislocation of the shoulder joint. The glenoid cavity into which the condyle, or head of the humerus, is articulated, is placed below one of those processes; and the lever of the bone, against which the collar-bone acts, is placed a little further from the body than this cavity. By this structure, the severest strain in pulling, pushing, or otherwise moving the extended arm, is thrown upon the blade-bone, though the peculiar curve of the collar-bone, and that of the process to which it is attached, enables it to give a firm support, and yet one which admits of considerable motion.

This is a part of the structure in which mammalia differ from each other, and also from birds; and, therefore, it must be well attended to. The two extremes of articulation for the shoulder, or rather of affording a support for its articulation, may be considered the nearest approximation to absolute rest on the one hand, and that which admits of free motion in the mesial plane, without any cross bone applied as a strut or tie, to restrict the motion of the glenoid cavity; that is, of the humeral end of the blade-bone on the other. The first is what we find in birds. In them the motion of flying, which is the essential motion of the anterior extremities of the class, not only does not require a free motion of the glenoid cavity; but it requires that this cavity should be as nearly as possible fixed in its position upon the body of the bird; because the powerful stroke which a wing requires to take in order to send a bird rapidly through the air, is inconsistent with any considerable degree of shake in the first joint of the wing. If motion proceeding or produced from any fulcrum, is to be vigorous and effective in proportion to the whole muscular force exerted, this fulcrum must be firm; and yet it is inconsistent with the contents of the chest, even in a bird, that the wing-joint should be articulated directly upon the walls of that. A tripod is therefore (see the article BIRD), provided for the articulation of the wing, and this tripod is firm, and bears equally upon its three branches in proportion as the action of the wing is to be vigorous. The three branches of the tripod; first, the blade-bone, placed on the upper part of the shoulder as in the mammalia, but more simple in its form, and less abundantly supplied with muscles; the coracoid bones, which connect the heads of the scapulars with the anterior angles of the sternum, and which, though separate bones and differently arranged, bear some analogy to the coracoid processes in mammalia; and the frenal bone which is applied to the heads of the blade-bones and coracoids, and keeps them asunder. This is the bone which answers to the clavicles in mammalia; and, as is the case among them, it is the bone which varies the most in form and strength according to the different kinds and degrees of action of the wing. The opposite extreme may be regarded as that in which the shoulder-blade has a free and extended motion, untrammelled by any connecting bone; this is the characteristic form in galloping animals, as in horses for instance. The blade-bone, though embedded in the flesh in these cases, may be said to be a part of the acting limb; and thus, in animals which are unfettered with clavicles in this part, the whole muscles of the shoulder come into play in the same action; and the spinous processes of the dorsal vertebræ form the points of support for the first series of muscles that come into play in the rapid motion of the limb. The human subject is intermediate between them; and the glenoid cavity can be moved round in a circle, though the chief motion is in the blade-bone, in consequence of its being free at its distal extremity from the joint, whereas the clavicle is tied to the sternum. The humerus, shoulder-bone, or more correctly the arm-bone, is connected with the blade-bone only at its upper extremity. It forms the strongest part of the arm, and has two tubercles, and also condyles on the extremity, most distant from the body. The two bones of the fore-arm are the ulna and radius. The ulna forms the elbow joint with the humerus, and the

radius acts against a tubercle, and gives a twisting or rotatory motion to the hand. Both these bones have cavities at their extremities for receiving the processes of those bones with which they are articulated; but they have also projecting processes which increase the lever power of the joints, and ridges in their length which give firm insertion to the muscles. The chief muscles that move the fingers as a whole, have their insertion on these bones.

It is scarcely possible to give a popular account of the bones of the wrist so as to make the mode of their action intelligible to ordinary readers. Generally speaking, they have sliding motions; and those motions are secondary, or only modifications in the direction of such motions as are communicated to the hand. With the exception of that one of the number which answers to the thumb, the metacarpal bones, that is, the bones of the palm, have comparatively little proper motion. Their chief purpose seems to be to support the tendons which move the fingers and thumb, and to afford a more extensive grasp. The latter use of them is illustrated by the fact that those mammalia whose hands are more exclusively grasping instruments, and not instruments of all work like the human hand, have this part of the structure more extended, and they grasp more firmly in proportion to their size than the human hand can grasp. The principal motions of the phalanges of the fingers and thumb are opening and shutting; but the fingers have some rolling motion on those joints by which they are articulated to the palm; so that a small circle may be described with the point of the finger, while its articulation with the palm, that is, the point to which it is articulated, remains perfectly at rest. This motion is more free in the fore finger than in any of the other three; and it is comparatively very free in the thumb, which is articulated upon a sort of universal joint, only it does not in a stiff hand extend far backwards. We shall, however, have occasion to speak of some of the articulations afterwards. The bones of the lower extremities have been in part already mentioned. The thigh bone is connected at its lower extremity with the upper end of the tibia, or principal bone of the leg; and the knee-pan lies over and strengthens the articulation in the manner which has been already described. The knee-joint between the thigh bone and the tibia is a hinge, formed by two processes of the upper bone acting in two cavities; and the head of the tibia is enlarged, in order to adapt it the better to the enlarged processes of the thigh bone. The external part of the head of this bone is the most enlarged; and to the enlargement of this the head of the fibula, or small bone of the leg, is applied; and this gives a slight twisting motion to the knee. The distal extremity of the tibia embraces the astragalus, or great articulating bone of the foot, on its upper surface, and also on its inner side, where an extended process forms the inner projecting bone of the ankle. The lower extremity of the fibula is applied on the other side, and forms the external projecting ankle bone. The enlarged process of the astragalus which forms the heel, and gives the limb a firm basis while the body is in a horizontal position, or bent in any direction, and still resting firmly on the foot, is peculiar to the human subject. The tarsal bones of the foot have sliding motions, something analogous to those of the wrist bones; and by means of them the foot can adapt itself to many forms of surface, and

maintain the balance of the body is a great number of attitudes. The metatarsal bones consist of five elongated phalanges, like the metacarpal ones; and the phalanges of the toes are equal in number to those in the fingers, only they are individually much shorter, and their motions are far more limited; and though the great toe has no grasping motion against the others, as the thumb has against the fingers, yet it may be educated to far more activity, and may acquire far more strength in its muscles than it has in those who use their feet for no other purposes than those of ordinary walking, and have them confined and not unfrequently cramped in shoes from their infancy. It has sometimes been said, and the analogy at least is in favour of the truth of the saying, that those who have been accustomed to go without shoes in their earlier days are more vigorous in the feet and retain the use of them longer than those who wear shoes from the beginning. Over the joints of the toes, and sometimes over those of the fingers, and especially the last joint of the thumb, there are sometimes little bones, formed not of diseased matter but in a quite healthy state. These last are called sesamoid bones, or milletseed bones; and it is understood that they act something in the same manner as the knee-pan, in strengthening the joints and increasing the facility of their motion.

Such are the bones of the human subject, in their arrangement, their application to each other, and their principal uses. We have noticed the principal modes in which bones are united by sutures, when it is not intended in the economy of the system that the one of them shall have a motion upon the other. We have also mentioned some of the forms of those parts of the moving bones which are applied to each other, but it may not be amiss to recapitulate the principal modes of those unions as they are usually stated in the books. Of unions of bones which have motion to a greater or less extent, there are two general classes: those which are only partially moveable, or partake something of the nature of sutures, and also of the nature of joints; and those which, whether moveable in one direction or in several, or moveable to a greater or less extent, have their motions free as far as they go. The first species of union is called *amphithrosis*, which means that they partake of one or of both of the modes of separation or of junction; and the second is called *diathrosis*, which means that the bones are completely divided from each other, unless in so far as they are bound together by ligaments. Cases of this last kind form the proper joints of all mammalia; and, therefore, they are of the greatest consequence in studying the action of animals, though the others are scarcely less important when we consider the adaptation of the animal structure to its own preservation, which is far from being the least interesting, or the least instructive point of view in which it can be regarded.

The first modification of amphithrosis is that in which the bones are simply united by cartilaginous matter. This mode of union is called *synchondrosis*, because both bones stand in the same relation to the uniting cartilaginous matter. Bones united in this manner do not, strictly speaking, admit of motion; but they yield to pressure much more than bones which are united by sutures. The different bones which compose the pelvis are instances of this kind of union.

There is a modification of the union by the mixture of elastic ligament with the cartilaginous matter which

admits of considerably more motion, and also is much stronger, than the mere cartilage. The vertebrae of the spine, already alluded to, are examples of this kind of union; and we may remark, that whenever flexure is given to a joint by muscular contraction, the joint straightens again by the reaction of the ligament whenever the muscular effort ceases. Ligaments more complete in their structure, and more extended than these, are employed in many parts of the structure of animals, as antagonists to muscles; and as the elasticity of the ligaments is a mere property of matter, and not an effort of the living principle, any repose, adhesion, or other result, which is brought about by means of an elastic ligament, is rest to the animal, and not fatigue. A third form of partial movement is that which gets the name of *syndermis*, which means that the bones are equally tied together by ligaments surrounding them, but that their surfaces are left free to slide upon each other. This is the case with bones which merely modify those motions which are conveyed across them by tendons reaching from one bone to another; and the most remarkable instances that the human body furnishes of these are the numerous little bones in the wrist and the instep, which modify but do not originate, by means of muscles attached to them, the motions of the hands and feet. When one bone is united to another by intervening muscles, and thus imbedded in the flesh, the technical name given to it is *sysarcosis*, which just means that the bone has its lodgment in the flesh; and of course it can move upon the other bones without the intervention of any thing else than those connecting muscles. The blade-bones are the most remarkable instances of this.

In *diathrosis*, there are three original and simple forms of articulation, with regard to the plane or planes in which the motions take place, and there is a fourth one which is compound. The first is the hinge-joint, which admits of motion in one plane only, that is, bending and extension of the limb or member, but not twisting or cross motion: the articulation of the occipital bone upon the atlas, the second and third joints of the fingers, and the joints of the elbow and knee, are chiefly of this kind, though the application of the second bone turns these, in part at least, into compound motions. The second form is rotatory motion, or motion in the same plane, all round and at right angles to the axis of the bones forming the joint: the articulation of the atlas upon the second or toothed vertebra of the neck is the most remarkable instance of this motion in the human body. A third form arises from the combination of these two, which may be produced by the peculiar form of the condyles and the cavities in which they act, or it may arise from a compound joint, where two bones act upon one, and the one of them tends to twist the other round, at the same time that the joint is bent: the articulation of the lower jaw in man and other mammalia, which have a grinding motion of the jaw, is an example of compound motion, produced by the form of the condyle, which allows one muscle to draw it laterally, while another is drawing it upwards or downwards; and all those joints in which a twist round and a flexure can be produced at the same time by means of two bones, as in the elbow, and to a less extent in the knee, are examples of the second form.

The last form, and that which admits of the most general motion, is the ball and socket joint, in which

the circular head of a bone is introduced into a cavity of a similar form. The most perfect ones of this kind are the articulations of the thigh bone with the hip bone, and that of the arm bone with the blade-bone, and there are less perfect instances in the thumbs. Very often, however, a motion of this kind is obtained by the intervention of a number of bones, which all contribute to the motion to some extent or other, though it is not very easy to assign each its proper share: the curious motions of the wrist, which may be said to be in all imaginable directions to which the members can be bent, are perhaps the most remarkable instance of this, not only in the human subject, but among the whole manimalia.

In those joints which have the most general motion, arising from the peculiar motion of two bones, there are two precautions against the chance of dislocation. The hip joint, which, though it is a ball and socket, still has its most powerful motion in the mesial plane, has the ball united to the middle of the socket by a round ligament, which partly forms a pad between the acting surfaces, and partly allows a more free motion, but prevents the bone from slipping out of its socket. Other joints, such as the joint of the knee, which have their principal motion hinge-ways by means of two condyles and two cavities, have a division between the condyles in which there are ligaments placed crossing each other, and allowing, at the same time, free motion to the joint. Such joints are generally also inclosed in ligamentous matter, which forms a border round the brim of the cavity, and extends over the condyle and part of the bone. These ligaments are, like the others, elastic, and when the joint is strongly bent in one direction, there is a tendency in the ligament to bring it back again, if the muscular action is suspended.

The position of repose, or perfectly easy rest, in animals which stretch themselves down to rest, assumes that of a uniform balance of the ligaments, at least in the limbs of the animal. The muscles are the portions of the animal structure which are soonest tired by exertion, and the position of rest at perfect ease is that in which all the muscles are equally in a state of repose; and any one may know whether a limb is in a state of complete repose or not by trying whether external force will bend it with equally little exertion in all the directions in which it naturally bends. Painters and others, who endeavour to represent the positions of animals and their parts, whether in a state of action or in a state of repose, often commit sad blunders from ignorance of the mechanical action of the animals. They often lay a figure down in repose, or even asleep, with all its limbs in a state of great muscular excitement; and they as often represent a limb as in the act of performing some mighty deed, when the said limb is in a state of perfect inaction. The most ludicrous blunder of this kind is that in which violent action is endeavoured to be represented; for, in these cases, an assassin may be represented as in the very act of selling his victim to the ground with a bludgeon, or of stabbing him to the heart with a dagger, and yet the muscles which extend the arm and those which draw it back may be both so equally excited in the representation that the arm could not possibly move a hairbreadth. We must, however, close our observations on the bones and their adaptation for motion, for to exhaust the subject, even on the human body alone, would be a vain expectation. What is already known would fill many

volumes, and the unknown would, in all probability, fill a far greater number.

THE MUSCLES. As the muscles, or immediate organs of motion, vary in their forms according to the state of action or repose that they are in, and as from their being wholly composed of soft animal matter they are subject to perish, or at all events to lose their original shape far sooner than the bones, we shall not go into even a list of them, but content ourselves with a few remarks on their nature and mode of action, and on those appendages which connect them with the parts which they move, or keep them in that shape in which they can perform their offices most effectively, and with the least exertion on the part of the animal.

Wherever a muscle appears, or to which ever of the functions of the animal it ministers, its general structure and general mode of action are the same, though from the number of different motions of which they are the organs, their shapes, sizes, and relative degrees of strength vary much.

Various divisions of the muscles into classes have been proposed, according to their supposed connexion with what is called the will of the animal, and also according to the fancied system in the animal of which they are supposed to form a part. Such distinctions are, however of little or no value. The question of will is one which should be introduced as seldom as possible, for this very plain reason, that nobody can tell what it means; and, instead of the muscles of the arm being voluntary or obedient to the will, and the muscles of the heart involuntary, or not obedient to it, the whole difference is, that the external one, exposed as it is, and temporary as it is in its use, is not so easily or so constantly excited to action as the internal muscle, which is defended from the air, preserved uniformly at a high temperature, and has the stimulus of the blood always applied to it in the course of the circulation. The real ground of distinction is, therefore, one concerning the causes which stimulate muscles; and as the actions which the different mammalia, to leave all other animals out of the question, have to perform in nature are perfectly innumerable, and as we know nothing about the stimulus or cause of action in the muscle farther than as we see of the animal which possesses it, and the circumstances which *appear* to us to stimulate the animal to action, we cannot draw the line of distinction between what is voluntary and what is not. So much, indeed, is this the fact, that even in our own case, where we may naturally be supposed to have the best information, we cannot confidently say that we are possessed of any thing called will, which comes in as a sort of third party between us and the circumstances under which we act in any given manner. At all events, will can never be of any practical use, unless it advances as far at least as *can*, and therefore it is not a fit subject for popular writing, and perhaps not for instructive writing of any kind.

The best way, therefore, is to disregard all those metaphysical or systematic distinctions, and deal with the muscles just as we do with the bones—that is, describe them according to their forms and situations in the body, and the functions which we see them perform, without ever troubling ourselves why a muscle produces motion and a bone does not, or why one muscle appears to perform one kind of motion and another not. In all the varied motions and actions of the animal body, the muscle, considered as sub-

stantive matter, can perform no action and originate no motion, unless we trace it downward as connected with the race from its original creation as a living creature, how often so ever it may have passed through the embryo state during the interval. All our inquiries respecting the action of muscles must, therefore, be confined to what they do, and the manner in which they do it, because, as to *why* they do it, we can get no information.

Muscles consist almost entirely of fleshy fibres, generally arranged parallel and formed into bundles, which bundles, as well as the more minute fibres of which they are composed, are all encased with cellular tissue. This tissue admits a ready passage to the numerous blood-vessels, nerves, and lymphatic vessels, with which muscles, in the mammalia at least, are always copiously provided. The bundles of fibres of which a muscle is composed, are variously disposed in the muscle. When they run longitudinally through the whole of it parallel to each other, it is called a straight muscle; but it is sometimes run obliquely across the general substance of the organ, sometimes they diverge from partitions dividing the muscle internally, and sometimes they are disposed in a circular manner. The last mentioned structure occurs in the iris of the eye, which, in diurnal mammalia, contracts to a point by the action of light; but the eyes of climbing animals, which are nocturnal, generally speaking contract to a vertical line, while those which range the surface of the ground often have the iris contracting in a horizontal line.

In all muscles which give motion to the limbs and other articulated parts of animals, it is the distal bone, or bone most remote from the body of the animal, or from the spinal column in the mammalia, that the muscle moves; and when there is a regular articulation, the distal bone is moved upon the proximal, or one nearest the body, or centre of articulation in the body. In order to make a distinction of these two in the mere naming of the parts to which the muscle is attached, it is usual to say that the proximal attachment is the origin of the muscle, and the distal attachment the insertion of it; and when such a muscle acts, the tendency of it is always to draw the point of its insertion towards the point of its origin. If, however, the distal part of the member with which the muscle is connected rests on a fulcrum whose resistance is greater than the weight of the animal, the animal must move upon the member, and not the member upon the animal. Thus, in the case of an animal rising from a recumbent or a bent position, or in the case of the straightening of a bent limb by muscular exertion, it is to the body of the animal that the motion is communicated, and the extremity of the straight line remains upon the ground, unless there is as much force in the muscular exertion as to project the animal fairly into the air by a leap. In all leaping, galloping, and jumping, and indeed in all kinds of progressive motion, the body of the animal is thus propelled by the action of the muscles against a resistance sufficient to overcome the weight or inertia of the animal's body. Thus, the reference to the origin and insertion of muscles applies only to their positions in the body of the animal, and not to the absolute kind of motion which may result from their exercise.

Sometimes the muscles are inserted directly upon the bones to which they give motion, and in this case a layer of tendinous or cartilaginous matter is the

means of their union. In the living animal this matter adheres firmly; but when the parts are exposed for a sufficient length of time to the action of boiling water, or even to maceration in cold water, the tendinous matter is partly converted into jelly and separates from the bone. In other cases, and indeed in the majority of cases, in those parts which have extensive motions, the muscle terminates in a tendon or cord; and this tendon, which is popularly called sinew, consists of substances more or less approaching the nature of ligament. These tendons are fibrous, though their fibres are not nearly so distinct as those of the muscles; and they are placed in various directions with reference to the fibres of the muscles themselves. Those tendons are not susceptible of motion like the muscles, neither are they so elastic as ligaments; but there are considerable differences in their consistency in different animals, and in different parts of the body of the same animals. When the tendons of a muscle lie in the same direction as the fibres of a muscle itself, they may be at either extremity of the muscle, or at both extremities of it, according to circumstances. The tendons sometimes also pass through the body of the muscles, either in the direction of the muscular fibres or across it; and sometimes there are several tendons connected with the same muscle. All these varieties are adaptations to the different kinds of motion which the muscle is intended to produce; and not unfrequently the tendon is continued for a considerable way, and over intermediate bones. The muscles of the fingers and toes afford instances of this, for their tendons are very long, the muscles being situated upon the bones of the fore arm in the case of the fingers, and upon the bones of the leg in the case of the toes. When the tendons of muscles are extended in this way, they generally pass over bones which modify their motion, and not unfrequently over joints which have proper muscles for their own movements. In these cases the tendons are tied into their places by ligaments which surround them, and keep them to their arrangement; and very often it is where there are such ligaments, that modifying bones, with sliding surfaces, diversify the effect ultimately produced upon the part which the long tendon connects with the muscle.

In all those muscles which immediately affect the bending of joints, there must be in the greater number of cases an action of muscle against muscle; and these opposed muscles are called the antagonists of each other; as, for instance, a muscle which bends a joint, and a muscle which stretches it in the opposite direction, are antagonists, and the first is called a flexor muscle, and the second an extensor. When the bending or contractory action of the part is more vigorous, or, which amounts to the same thing, more important in the action of the animal, the flexor muscle is always the stronger; but when the extension of the part is the chief action, the flexor muscle is the weaker. The muscles in the human body are very numerous, very varied in themselves, and in the kinds of motion which they produce; but in the case of the individual fibre, the bundle, or the congeries of bundles, of which the several portions are separated from each other by tendinous septa, the action of the muscle is always the same—namely, the pulling together of its opposite extremities, by the shortening and swelling out of the fibrous part, and the extension of it in length by the subsidence of the contraction, and the relaxing of the muscle and its tendons.

Whatever may be the specific process, and the immediate means by which muscular contraction is produced or excited, it evidently has some connexion with electric action, and indeed with merely rapid motion of anything which is fatal to life. Persons who are killed by lightning have all the muscles relaxed, and the body rendered as loose and feeble as though the whole soft parts were deprived of their cohesive power. It is nearly the same with those who are killed in battle by gun-shot wounds, for they also are relaxed, and have no expression of any strong passion on their countenances after death; whereas the countenances of those who are killed by wounds with cutting instruments, set rigidly in death with that expression of rage, agony, or whatever strong passion under the influence of which they cease to live. Those results of the rapid concussion of the lightning, and the rapid stroke of the bullet, have been too frequently noticed for leaving any doubt of their truth; and as the lightning and the leaden bullet have nothing in common but the rapidity of their motion; for the one produces its effects by a mere shock, and the other by a mechanical wound, it is difficult to avoid concluding that it is from this sudden assailing of the system, that two causes, apparently so different, produce the same effect upon the muscles.

This, by the way, is one strong ground for concluding that they have a general connexion in this rapidity of motion; and that the animal life which they destroy belongs to the same general class, although, as it acts through the medium of a very different apparatus, its displays are correspondingly different. What is called the wind of a spent cannon ball, which often stuns for a time, and not unfrequently destroys life altogether, must be regarded as acting in nearly a similar manner upon the sensibility of the whole living structure of the body; and in the case of man, we have results very similar, produced by sudden and violent mental excitements. Every one must have heard of how effectually a sudden panic turns the bravest men into perfect cowards, or how sudden fear, even when the ground of it is purely imaginary, will unnerve the arm, strike the tongue dumb, and hold the individual rivetted to the spot, and powerless against even the feeblest enemy, and very often when there is no real enemy in the case at all. We cannot suppose that, in the case of human beings, these are primary affections of the mind; because it should seem that the mind can be affected by external nature only through the instrumentality of the senses: and therefore we might be prepared to expect that similar cases of the influence of intimidation might be found among the other animals. Something of this sort occurs in what is usually termed fascination. The accounts which have been given upon this subject must be all received with some degree of caution, because, generally speaking, they bear the stamp of extreme credulity upon them. But still they are so many, and a number of them are given with such apparent claims to probability in many parts, that it would be perhaps carrying scepticism to an excess to deny the whole, though it would be equally wrong to give the whole implicit credit. All the facts, however, seem to point to the general conclusion, that there is a remarkable agreement in many particulars, among all the various modifications of action, the effects of which present themselves in the material world.

But though the muscular action of animals may be the same in kind with every other denomination of

action, the effect of which is to produce motion, this does not lead us one jot nearer to the origin of the animal action than we were before. We know that the first rudiment which we have of every animal capable of awakening into life, and growing by proper nourishment into the general resemblance of a species, is the result of an act on the part of animals of the same species; and we know farther, that if we endeavour to extend the performance of this act beyond the species, there is a limit at which it fails, not only in its effect, but in the tendency towards its performance; and therefore how much soever we may have reason to conclude that the action of animals is in principle the same with all other kinds of action in matter, we are utterly unable to say why the result should be an animal of one species and not of another, or indeed why it should be an animal at all.

OTHER ORGANS OF ANIMALS.—The other organs of animals, besides the external ones which we have mentioned, and the general structure upon which the external action and adaptation in nature of animals, and especially the mammalia, depend, may be referred to certain classes, each class being more immediately fitted for the performance of some one particular part of the animal's economy, though they all harmonise with, and support each other in such a manner as to show that how complicated soever the organisation may be, the animal is still one, and that not one of the functions performed by those different systems of organs which belong to it could be carried on without the others; though there is still that play of the system and adaptation to contingencies here, which we find to run through the whole.

Those systems of organs need not detain us long, for some of them have been alluded to in previous articles of the present work, and others can be more conveniently taken along with the notices of those divisions of the mammalia of which they form characteristic features. The organs of nourishment have received sufficient illustration in the general article **ASSIMILATION**, and the variations can be better appreciated in contrasting the animals wherein they appear. A mouth for receiving the food, a gullet for transmitting it, a stomach more or less complicated according to the species for its digestion, an intestinal canal, certain separate glands for preparing liquids which promote action in that canal, absorbents to take up the food from the canal, and leave the impurities, and an apparatus for further elaborating the new matter so taken up, and conveying it, along probably with part of the exhausted matter brought back by the lymphatics, into the mass of the blood, are common to the whole of the mammalia. In like manner, there is a common mode of respiration, or of applying the blood which has been mixed with the new matter and the matter of the lymphatics, to the action of atmospheric air, in order that it may deliver out a certain portion of carbon to the oxygen of the atmosphere, which is common to all the mammalia, and is in every case performed by receiving atmospheric air into cellular lungs, along the walls and passages of which blood vessels are ramified with an extreme degree of minuteness. The quantity of respiration, and the rapidity of circulation, vary a good deal in different species, and in the same species, and even the same individual under different circumstances; but still the general mode is the same throughout the whole class; and both in their increase and their decrease, to what cause soever the one or the other may be owing,

they keep pace with each other. The respiration of the mammalia is always accompanied by voice of some kind or other, but though in many of them the organs of voice bear a much closer resemblance to man than those of other classes of animals, and especially than those of birds, yet none of the mammalia have ever been taught to articulate, or to imitate sounds, although many birds are capable of being taught to utter words, and to execute pieces of music with very great perfection. This unquestionably does not happen from any inferiority of resources, or what is usually called animal sagacity; for in these respects the mammalia stand far higher than any other animals. As they do in other respects, so in this, they differ greatly from each other; but in the whole of them there is an expression in the eye, a readiness in the ear, and an aptitude to take notice of circumstances around them far superior to what is to be found in any of the other classes. They also readily know persons and places, and they understand sounds, and feel pleasure at some, while they are irritated by others. It should seem, therefore, that their inability to imitate sounds, and especially articulate sounds, is a matter of organisation merely, and has nothing to do with the system of sensation. Indeed we have something nearly corresponding to this, for the most eloquent speakers are rarely the most acute or profound thinkers; and it is at least not proverbial that those who have the sweetest voices have the best understandings.

The allocated organs of particular senses are the same in number and in situation, making allowance for differences in the general form of the body, in all the mammalia. The ears are always two in number, farthest backward on the upper or lateral part of the cranium; but they differ greatly in their development and their external form, according to the extent to which the animal has occasion for the sense of hearing, and the times and places when that sense is exercised. The eyes follow next in advance; but their position varies according to the direction in which the animal has most occasion to exercise the sense of sight; and many circumstances also tend to vary their size, mode of action, and intensity of perception. The organs of smell have also their general situation similar in the whole; and so have the organs of tasting; though both of these vary much in the degree of their acuteness. What is usually termed the sense of touch, or of feeling, is a very doubtful matter, and one of which it is by no means easy to give a general explanation which will meet all the points, or even be very satisfactory upon any one of them. This sense ought, strictly speaking, to include not only those sensations which we fancy that we derive from touching substances with our hands, such as roughness and smoothness, hardness and softness, heat and cold, and the like; but it ought to include all sensations which we can consider as being pleasurable or painful, or in any way perceptible, except those sensations which we refer to distinct organs, and lose if those organs are destroyed or seriously deranged. Among these last ought to be numbered those influences of the atmosphere, which affect us deeply in proportion to our sensibility, but which we cannot refer to a sense of touch, as connected with peculiar and localised organs, any more than we can refer them to the other senses. The feeling of high health and buoyant spirits, and also all the opposite feelings down to absolute internal pain, of which we are often unable to describe the seat, should also be

included under this head, or else the sense of touch ought to be subdivided into as many branches as there are different sensations which impress us, not through those local organs to which particular senses are attributed.

When we consider carefully the circumstances now mentioned, and bear in mind how many different circumstances affect our bodily comfort, without having any thing of a mental nature in them that we can discover; and further, when we bear in mind how very often we are thus affected pleasantly or painfully, when we can trace the affection to no source, observed as physical, or suggested as intellectual, we can hardly help admitting that we ought to give this sense, one modification of which we call touch, as extensive a locality as the whole sentient structures of our body, and perhaps even those which we do not usually at least consider as being possessed of any capability of sensation. The senses which have local organs, the destruction of which puts an end to the sense, do not participate with each other, unless perhaps in that curious connexion which subsists between smelling and tasting; but this general sensation belongs to the organs of the allocated senses as well as to the other parts of the body; and often, as they are more finely organised than structures of more rude employment, they are the very first to be affected. The converse holds equally good; for this general sense may be excited, and that to a degree highly pleasurable or highly painful by the exercise of those allocated senses upon particular objects. There are sights and sounds, and odours, and even savours, which can make the whole frame thrill with delight; and there are others in each of the four classes which can make it shudder with horror. All this may happen too without any suggestion of relation which can give us the slightest ground for believing that the matter is a mental one; and thus we are constrained to look upon it as a mere affection of the sentient body by external circumstances.

Such being the case, it follows by a most natural analogy, that this general sense of the living structure must be common to all the mammalia, only varying in acuteness with the species, and indeed with the individual; it must do the latter of these as well as the former; for if we find this general sensibility, as we may term it, so variable among the human race, as the observation of every day proves it to be, we cannot expect to find perfect uniformity among the individuals of any species of mammalia whatever.

When, therefore, we speak about the sense of touch in these animals, we must be careful not to fall into error, and suppose that it necessarily belongs to some particular kind of surface, such as a naked skin covered with small papillæ; for the sensation can be conveyed as readily by a hair, a bristle, a porcupine's spike, or even the horn of an ox, as by the most delicate finger belonging to the human race. We know that the whiskers of nocturnal animals, and probably the whiskers of all animals which have such appendages, communicate a sense of the presence, and even the approach of objects, with wonderful quickness. The hair of horses, and indeed that of all animals, respecting which the experiment is properly made, give proofs that they are possessed of equal sensibility to external objects. The sensibility of leaping animals to friction, calculated to produce voltaic action in their fur, is well known, from the familiar experiment of rubbing a cat's back against the grain; and in order to show the perfect identity

of the two kinds of excitement, we invariably find that parts are most readily obtained from the cat's back in those states of the atmosphere best adapted for the working of a common electric machine. The sensibility of many of the mammalia to atmospheric changes, even when those changes are too slight for telling upon our feelings or upon our instruments, are also well known; and in this way the almost eyeless mole, lodged under the surface of the ground, is probably a more certain "weather-wiser" than the most zealous human student of the science of meteorology. Upon this branch of the system, as well as upon the others, we may therefore say that the system of sensation is the same in kind among all the mammalia, and only varies in degree in the different parts, so as to adapt each species to its proper haunt and habit in the most perfect manner.

Even in the external coverings of their bodies there is a characteristic resemblance among all the mammalia, in which they differ from all other animals, and which, if it is known in the case of one can never be mistaken in that of another. The skin of the mammalia is very thin in some species, and very thick in others; but still in the whole it consists of the same number of parts similar in their composition and their arrangement. Whatever appendages grow from this skin for protection to the animal, or for any other purpose, are always substantially the same. They may be of exceedingly delicate texture as we find in many of the fur animals, and in the fleeces of some of the finer-woolled sheep, or they may be coarse and shaggy, of which we have examples in the produced hair of the American bison and the mane of the lion. They may also have that appearance which we find in the substance called whalebone, or more correctly baleen, which forms the apparatus used by toothless whales for capturing their food; it may be tubular, with an opening in the centre, as we find it in the ornithorhynchus and some other animals; it may be in hard spines, which have their insertion into cavities, as in the porcupine, the echidna, the spiny rats, and some others; it may be an agglutination of fibres without any core, as we find in the horn of the rhinoceros, or it may be a casement of horny matter upon a core of bone, as we find in the ox, and all those other animals which have true horns; and, according to the species, it may differ in its consistency, and also in the proportions of its ingredients, but it is still substantially the same substance; and whether it appears in the form of fur, of wool, of hair, of bristle, of horn, of hoof, or claw, or of nail, it is still substantially the same, and when examining it we could at once pronounce it to be a product of the skin of the mammalia in one or other of the species, and not any thing else.

Thus, notwithstanding all the diversity which there is in the size, the structure, and the habits of this class of animals, there is in every part of them a general character which prevents us from confounding them with any other animals; and this character pervades their whole organisation, and is traceable in all their habits.

In the mode of their reproduction—the means which have been given them for the continuation of their several species, there is the same uniformity. Every species consists of two sexes, and each individual is of one sex only. Instances are indeed mentioned of the appearance of a double sex; but these instances, which are rare, are always monstrous formations, and whatever may be their appearance they

never have a double function, and very often they have no function at all. Some physiological facts connected with this part of the subject are very curious, but at the same time perfectly inexplicable upon any principles with which we are acquainted. One of the most familiar, and at the same time perhaps one of the most singular, is the case of "free martens." Hitherto we believe the occurrence of them has been found in no animal save the common domestic ox, and no reason can be assigned for its occurrence in that animal. One young one is understood as being the regular or normal number produced at a birth in this species of animal, but there are sometimes two. If these two are both males or both females, they follow the ordinary law, and are perfect animals; but if the one of them is a male and the other a female, the female is imperfect or a free martens; and differs not only in its general expression but in its flesh from the perfect animal, whether male or female, being accounted far superior to either of them as food, even though they are mutilated very soon after their birth.

There is another remarkable distinction in the mode of reproduction in the mammalia, and that is the difference between placental animals and marsupial ones. The latter have not yet been completely investigated; and for much of what is known respecting them we may refer the reader to the article *ΚΑΝΟΑΧΟΟ*. But, independently of the difference of structure requisite for the double gestation of marsupial animals, there is a characteristic distinction of a more general kind between them and the placental mammalia, that bring forth their young in full maturity. Their appearance as to form wants the elegance and litheness of the others. They are shapeless animals so to speak, and the very covering of their bodies is different, though it is not very easy to speak particularly of what the difference consists. The most remarkable distinction between them and the others, however, is in the expression. The eyes of all marsupial animals look blank and vacant, and though physiognomy is not perfectly understood, and consequently our opinions concerning it cannot always be trusted, yet the whole air of the head, as well as the general shape of the body, give us at once the impression that marsupial animals are stupid and resourceless. Even the feet, which one would suppose to be less affected by physiological differences than any other parts, are different from those of the common or characteristic mammalia, and in many of the species they bear some resemblance to the feet of birds or those of reptiles. The anatomical structure has not been examined with the requisite degree of attention; but it should seem that there is an inferiority in the tarsal and carpal parts of the extremities, and that the foot, for whatever kind of work it may be adapted, is always inferior to that of the placental mammalia.

But notwithstanding the differences of appearance, expression, and intelligence, which follow this difference in the production of these animals, their predominating character is still that of the mammalia, and therefore in what light soever we view the numerous species which constitute the class, we must always come to the conclusion that it is clear and well defined in its general characters.

SEC. II.—PHYSIOLOGY OF MAMMALIA.—Physiology literally means "the voice of nature," but in general it is restricted to nature as organised, and thus it becomes "the voice of life," and is divided into two

parts answering to the two great divisions of organic nature, vegetables and animals. With the former we have, in the mean time, no concern. Our view of the latter must also be principally directed towards one class of animals; but as that class, the mammalia, are those in which the system of sensation, which is the grand character of animals, and that which at once distinguishes them from vegetables, is most fully developed, their physiology in a great measure includes that of those other classes whose sensation is inferior.

In the proper, that is the most useful sense of the term, animal physiology is the science of life, or of the investigation of all the phenomena of living beings, and the causes of those phenomena, as far as such causes are capable of being known. The phenomena are of course as open to our observation in the animal world as they are in the vegetable or the inorganic; and as they approximate more nearly to our own personal phenomena than the others do, and are also in themselves more striking, they occupy more of our attention, and there is perhaps no individual of the human race, however uncultivated and however careless, who is not at some times an animal physiologist. Nor is it at all to be wondered at that such should be the case, for when we come to think seriously of it, there is something truly wonderful in an animal; and if it were possible to imagine a human being possessed of the average degree of intelligence, that had lived to the years of careful observation and calm reflection, without ever having seen an animal, and then to have one brought before him for the first time, it is not easy to find words expressive of the surprise and the delight which such a novelty would produce. All the spectacles and shows, after which the restless minds of the idle and unthinking pant and toil with so much solicitude, would sink into perfect insignificance before this especial wonder; and the individual in the circumstance which we here suppose would fancy he possessed in the animal a treasure of knowledge which could not be exhausted.

We have practical evidence of this in the case and conduct of the young, of simple country people, and of all whose minds have not been debased by that love and pursuit of sensual gratification and frivolity which are the curse of the majority of mankind in all ages, and in none more than in those societies and states of society which lay claim to superior degrees of civilisation and refinement, but in which, in reality, by far the greater majority spend their lives in "sowing the wind and reaping the whirlwind." When we observe those unsophisticated persons examining a new animal, that is, an animal new to them, they present to us a lesson of genuine wisdom, if we, in the pride of our fancied superiority, would but deign to learn it. It is not the unwonted shape or peculiar structure of the animal which rivets their attention, it is "what the animal does"—the display of the principle of life in it—the phenomenon of that mysterious power, veiled in its essence from mortal ken, which, generally speaking, makes the mass of matter before their eyes an animal and not any thing else; and, in its peculiar modification, makes it the particular species of animal before them, and not another. Ask any person of the description alluded to, upon returning from a menagerie, or even from a common show of wild beasts at a fair, what he has seen, and the answer will never be concerning modification of shape or diversity of colour; it will invariably run upon the action of the animals, and it will be expressed

with admiration and delight in proportion as that action is novel and energetic. The common exhibitors, who address themselves to the least learned class of the population, are well aware of this, and never fail in turning it to the proper advantage. They plaster pictorial representations upon the display canvas in forms which the wildest imagination never fancied, and in attitudes which set every principle of equilibrium at defiance. But though these attract the first gaze of the rustic, they do not constitute the spell which beguiles him of his hard-earned pence, and betrays him within the deceptive booth: there are two short words—"all alive"—which are the real attraction, and the irresistible desire is to know what shapes so marvellous *can do*.

This is an every day and a homely illustration; but the instruction which it is capable of affording, and which it affords largely, is not the less valuable upon this account. It will be remarked too, that in those cases, mammalia always attract more attention than animals of any other class. Birds may be ever so elegant in their shapes, and ever so gay in their colours; and the folds of serpents may be represented as though they could break bars of iron, and their mouths (some of which are abundantly wide naturally) as much distended as though they could swallow elephants; but if the rubric presents any novelty in the mammalia, although not larger than a rabbit, and equally simple in its expression, the eye of the rustic ultimately settles upon that, and it even in its simplicity tempts him more than all the beauties and all the monsters of the other classes of animals, heightened as the latter are by every exaggeration to which a paint brush, unfettered by taste of any description, can have recourse.

Evidence obtained from sources such as those now mentioned, whatever may be its intrinsic value, is always genuine, being free from the contamination of theory and system of every sort. Therefore, whether the distance it carries us be shorter or longer, we can always depend upon it so far as it goes. The specimen of mammalia, we have said (and any one who chooses to make the observation may verify the saying), is the real attraction. Why is it so? This is a simple question, but the answer to it is very important: it is so because, from what the rustic has already observed in the course of his personal experience, he expects to find a greater display of the phenomena of life, or of the living principle in that specimen of mammalia than in all the animals of the other classes. This familiar illustration, and we have endeavoured to draw it from a source as little connected with artificial learning as possible, is certainly the most sincere, and far from the least convincing proof of the superior interest and value of physiology (we mean animal physiology) that could be adduced.

When we come to this department of study we find that we are upon new ground, and that there is something in addition to all that we meet with in mere matter and its laws, which those laws will not explain. The unorganised body, under what form soever it may exist, is wholly under the government of the laws of matter, which laws we can reduce to mathematical proportions in their different instances, and state them by weight or measure; and whenever one substance of this kind acts upon another, or two act jointly, so as to produce a new substance by their union, the whole materials of that new substance are ready prepared before the act of union, and after that

act is completed, the resulting substance is in itself as passive as any of the parts of which it is composed. If we expose it to the air and the weather, to which all mammalia are more or less exposed, otherwise they cannot perform their functions—if we expose it to these, their effects upon it is in all cases a decomposing or otherwise destructive one. There is no principle of reproduction, no faculty of growth, and no means of preservation in the inorganic or dead substance. It is perfectly passive to those physical laws which it is the province of natural philosophy and chemistry to discover; and were we acquainted with the whole of those laws, we should be intimately acquainted with the nature of every organic substance, and could foretell the exact change which under any given circumstances it would undergo, with the same certainty as we can predict that fire will burn dry wood, lead melt at a certain degree of heat, and water crystallise into ice at a certain degree of cold.

In these inorganic or dead matters there is, therefore, strictly speaking, no physiology; the individuals or the kinds have no story to tell, for the whole of their story is told in the physical laws of matter, and, for the sake of illustration, it may be said that those laws are inexorable despots to whom all the species of inorganic matter yield the most implicit obedience.

When however, we come to animals, and especially to the mammalia, which are, as we have said, the most typical animals, we find the case very different. The physical laws of matter, taken generally, will not only not explain their phenomena, but these phenomena are displayed in spite of the physical laws of matter, and, in opposition to them, by the triumph of a greater power over them as it were. This is true of the very materials of the animal body. The animal, or the principle of animal life—that unseen power which we cannot describe except through the medium of its phenomena—cannot change the physical nature of any one substance, considered as a simple substance, which enters into its composition. Carbon, for instance, is exactly the same substance in the body of a living animal as it is in a diamond, in the charcoal of burnt wood, or in any mineral carbonate, or compound of a carbonate. The oxygen and the hydrogen which exist in the structures of an animal are also exactly the same as they exist in water, or in any oxide or any hydrate whatever. The same may be said of the nitrogen, and of all the other elements which enter into the composition of the animal body. And, as the action of the animal has no power of changing the nature of any one elementary substance, so it has not the power either of producing or of finally destroying any one elementary matter; so that, when an animal of the largest size, the most active character, and the longest life, ceases to exist, it leaves the quantity of matter, and the proportions of those kinds of matter which we call elementary, in precisely the same state that they were at the dawn of its first rudimental existence.

But though this is unquestionably true, and though it is a truth necessary to a proper understanding of the first and simplest principles in animal physiology—the principle upon which all our knowledge of a subject so difficult and so apt to tempt us astray must be grounded—yet we must be careful as to what we understand by elementary matter of whatever kind. For our purpose it is not necessary to inquire how many kinds of elementary matter there are, or whether

any one of those substances which the art of the chemist has not hitherto been able to resolve into parts, differing in their qualities from each other, is or is not a simple element, and absolutely indecomposable. The practice belongs to the chemist, and is in itself a physical matter and not a physiological one; and being a physical matter, information concerning it must be sought in those physical laws of matter which, as we have said, are opposed and overcome by the law of life in the individual animal as long as its life continues. The principle is all that the physiologist is concerned with; but it is especially necessary that his knowledge of this should be clear and distinct, because the common loose expressions about animal matter and vegetable matter, and matter which is neither vegetable nor animal; and also the distinctive names given to imaginary kinds of animal matter, such as the matter of bones, the matter of membranes, the matter of blood, the matter of nerves, and an endless variety of others, are sure to mislead us if we do not clearly understand that they are simply conventional expressions.

When we speak of substantive matter as existent, and obedient to the laws of matter and nothing more, then there can be no such thing as *animal* matter, because there must be something in addition both to those laws and to the matter before there can be the smallest part of the very smallest animal. When, too, we speak of the different kinds of animal matter, of those above alluded to, or others according to the structure to which we refer, we do not mean different kinds of substantive existence as merely matter, and under the physical laws of matter and nothing more. The real meaning of such expressions is, that each of the compounds to which we allude is the result of some degree or mode of animal action, wherein the laws of mere matter have been subdued and suspended for a time.

In the general expression, “animal matter,” our real meaning, when we have any meaning at all (for we are very apt to use such words without meaning), is that this matter displays the result of the action of animal life; and when we speak of a particular kind of animal matter, as, for instance, of the matter of bones, all that we mean is, that a particular kind or modification of the action of animal life is displayed in the matter of which we speak.

Even the words, “action of animal life,” though we cannot well refrain from using them upon some occasions, inasmuch as the life of one animal displays many species of action, are not altogether free from objection. Our conceptions of life in animals, though different in their subject, are similar in their nature to our conceptions of mind in man: we know nothing of the essence either of the one or the other, but merely their successive states; and that which we call the life of an animal, whatever it may be to our thoughts, is nothing to our observation but the succession of actions which that animal performs. Some of those actions are, however, so very different in their nature from any action which we can attribute to mind, as a thinking principle, that we naturally make a very broad and clear distinction between the two. Mind is capable of knowing matter, and turning its experimental knowledge to account, whether sensation be immediately concerned in this application of experience or not; but mind is not capable of acting upon matter so as to counteract or suspend any of those laws which belong to matter. It is emphatically said in

the sacred volume, that "no man, by taking thought, can add a cubit to his stature," and there is a great deal of philosophical truth in the saying. The mind of a human being has not the least controul over the character or appearance of any one part of the human body, unless in so far as experience may have taught it to use physical means for such a purpose; and if this is the case with regard to the matter and material structure of the body with which it is so intimately though mysteriously connected, much more must it be the case with all matter external of the body.

The principle involved in this is not an unimportant one. We know nothing substantive but matter, and can form no notion of any kind of substance except material substance, and therefore our conceptions of the nature of mind, and also of the nature of that which we call animal life, must be made up of negatives: we can tell what they are not, but we cannot tell what they are; and as the negative in respect of both is much the same with relation to substantive matter, it is very desirable that we should have some means of discriminating between the two, and understanding precisely the difference between them; for if we do not, we are in constant danger of confounding them together; and as a good many of the actions of those mammalia which have the most sensation and the most numerous resources have a great deal of similarity to actions performed by human beings, we are in great danger of considering the difference between mind and animal life as being a difference in degree only, and not an essential difference in nature.

When, however, we view the relations in which the two stand to matter, and the laws of matter, we readily perceive the difference. Mind, as we have said, has the faculty of knowing matter; but it cannot, without the instrumentality of some material means, the employment of some material agent of which it has acquired a knowledge by experience, produce the least effect upon matter, or suspend or counteract, to the smallest extent, even the most simple physical law. It has the knowledge of matter, and it is the nature of knowledge that it does not perish with that which is known. New objects, indeed, are so repeatedly drawing our attention in this world, and we have such a scramble to supply the real and artificial wants of the body, and all those other demands which the customs of society impose upon us, that we do not heed many things that were once known to us. But, even in these cases, there is no absolute loss or oblivion of the knowledge, for the most trifling circumstance will, if we were once acquainted with it, return, as we say, to our recollection, and that frequently by means which we cannot understand. All material things can pass into new forms, by entering into new combinations, and when the new form is assumed, the old one is gone for ever, and can no more be recalled than the noon of yesterday can be brought back to illuminate the midnight of to-morrow. But knowledge, of whatsoever it may be the knowledge, cannot thus be obliterated or cease to exist by passing into any new combination. It is true that we can and do, in many instances, obtain new knowledge by combining together, or rather comparing together, different portions of knowledge previously acquired. But this bears no analogy whatever to what takes place in combining matter, for the new knowledge is not composed of the previous

knowledge which leads to it, and the previous knowledge is not lost, or clouded, or confounded by the additional knowledge to which it has pointed out the way. Every portion of it stands as entire and unmixed as if nothing but itself were known; nor are there any means by which we can contrive to bury in oblivion that which we once knew; and every one must have felt that the more we labour to forget any thing, we just remember it the better.

The characteristic of mind, that in which alone it does or can display itself, is thus of an immortal nature, and cannot be lost or have its properties obliterated in a compound, as can happen to every kind of matter with which we are acquainted. A portion of knowledge cannot, in fact, be a compound; for whatever be the subject known, the knowledge of it is one and simple. The ancients, for instance, knew atmospheric air as a simple substance, and water as another, and from this supposed simplicity they called both elements of mere compound substances. We know atmospheric air as a compound of oxygen and nitrogen, and water as a compound of oxygen and hydrogen; and we also know that, as they exist in nature, both of these, generally speaking, contain other matters. But our knowledge of air or of water is not, in itself and considered as an act or state of the mind, any more compound than the knowledge which the ancients possessed of the same substances, when they believed them both to be simple and elementary.

Knowledge is, therefore, in its very nature simple—incapable of combination in the sense in which we apply that term to matter, and not material; and it follows, by necessary consequence, that knowledge is immortal—that is, it cannot be destroyed by the operation of any cause which affects matter, or by all such causes acting together—that it can yield to nothing save the power of One who could command matter to be where matter did not previously exist, and command matter to depart and leave nothing in its stead.

Now, if the only manifestation which we have of mind, namely—that of knowing, or being possessed of knowledge, is of an indestructible and, therefore, immortal nature, it must follow that this must be an essential attribute of mind itself; because whatever is known only from the demonstrations that we have of it in its effects as an active principle, must necessarily be regarded as possessing any one property, whatever it may be, which is common to and inseparable from all those effects. But all the evidences which we have or can have of the existence of the human mind are of an immortal nature, being knowledge, and nothing but knowledge; and, consequently, from this alone, and without any other argument or proof, natural or revealed, it is impossible for us to come to any other conclusion than that the human mind is of an immortal nature, not resolvable into parts, or decomposable by the operation of any or of all the secondary causes or energies of created existences that can be named, subject only to the direct fiat of its Maker; and as we can by possibility know nothing of the work of creation, or production without materials, so we can know nothing of the counter-work of annihilation in the ceasing to be of that which once existed.

This a point, the clear understanding of which is of the utmost importance, if we wish to possess rational views on the subject of animal physiology.

No matter how high, according to an estimate, the animal may be in the scale, the action of the animal still belongs to matter, and may mingle with and be blended and lost in the general mass of material action, just as the substantive matter which composes the body of the animal may, in whole after death, or gradually and successively during life, be blended with and lose in the general mass of substantive matter. It is evident from the facts, and it ought to be distinctly understood, that animal life, or animal power, or whatever we may call that which evolves an animal from its embryo, brings it to perfection, and ultimately renders it up to mingle with the dust, merely acts upon matter, but has no knowledge of matter in that sense in which we speak of knowledge as the only demonstrative attribute of mind.

We have a proof of this in the daily economy of our own bodies : when we are young and increasing in size, there is of course an addition to our frame of all those different kinds of matter that enter into the composition of the parts which are increased. But we have in ourselves no knowledge that this is going on ; and even at the period of our lives when our increase in bodily volume is most rapid, we have no knowledge that we are growing. So, also, throughout the whole period of life, when matter unfit for living action is removed, and new matter introduced to supply its place, we have not the least knowledge of what occurs ; and though it is probable that in the course of a very few years the whole matter of the body is removed and replaced by new matter, we are not in the least aware of the occurrence even of the one or of the other. Now, if in our animal system we have no knowledge of the matter which ministers to our growth, or that which repairs the waste of our system, it would be contrary to all the principles of reason and judgment to suppose that, considered as animals, we could have any knowledge of matter or its actions or changes, external of our own bodies.

Thus what we actually feel in ourselves is quite sufficient to guide our judgment in drawing the distinction between mental and animal action, and enabling us to give full scope to our animal physiology, without allowing it in the least to interfere with the physiology of mind. We can no more give a specific description of the animal power, than we can do of the mental power, for we know nothing about powers of any kind, farther than what we see in the effects which they produce ; but we know that the animal power invariably acts upon matter without having any knowledge of matter ; while the mental power knows matter without having any capacity of acting upon matter, and this is a sufficient distinction.

But although the animal, or the power or energy which exists in the animal, is inscrutable to our senses, and we cannot describe it as we describe material existence, yet we cannot help believing of it that it is mortal, capable of existing only for a limited time in one organisation which it elaborates for itself ; and when it is as it were exhausted and worn out in the individual by the continual struggle which it maintains with the physical properties of matter during its life, it must pass again through the embryo state, and appear a new creature, though identical with and species of the parent. This limit, which ties it down to the species, we can no more understand than we can understand why there are specific differences in inanimate and inorganic matter ; but we can observe the

fact in both cases, and it is as determinate in the one as in the other.

Although, therefore, our consideration of animal physiology is entirely separated from the physiology of mind, and shown to be totally different from it in its nature, even in the human subject, in which the two exist in combination ; yet we require to advert to very different causes in the physiology of animals from any which we meet with in the philosophy of inorganic matter. In the last, the causes which we have to consider are all *physical* ; but in the other they are what may be called *final* ; that is, causes which are to be inferred from the purpose which their operation accomplishes. The animal is a sort of warfare against the common laws of nature in mere matter : it grows in opposition to those laws, and it lives and performs its functions in opposition to them ; so that in the study of it we have to advert to assimilating and conserving faculties, which have nothing to do with the physical operations of matter, whether mechanical or chemical. The temporary or mortal power of the animal is proved by the fact, that it can maintain this warfare against the common laws of matter only for a time ; and though this time is very different in different species of animals, we cannot predicate immortality of it in any one particular case. It is not found except where there is both a combination of matter and an organisation of matter ; that is, a distribution of matter in a particular form, which it would not assume were it not for the principle of animal life ; and therefore, though during the exercise of this principle, the merely mechanical and chemical powers of matter are subdued, the principle of animal life is so intimately connected with matter, that it is impossible to separate the one from the other.

We must allow that there is not only a general principle of animalisation, but that there are as many distinctions or diversities of this principle dependent on itself, as there are species of animals in the world ; because we find that the line of distinction between species and species cannot be broken. But while we admit this, we must also admit that the laws of matter exercise their power upon the material substance of animals in the exact proportion that the animal power allows them so to operate. There is no capacity in the one to originate the other ; and as an animal cannot create matter, or change the nature or form of elementary matter, so neither can matter of itself originate any animal how simple soever. In every case there is an embryo, an alimentary animal being wanted, and it is not a little remarkable, or confirmatory of the principle for which we are arguing, that the care of this embryo, and the connexion which it has with an antecedent animal life, are always in proportion to the development of animal energy, or the deviation of the animal considered as a piece of matter from the common mass of inanimate matter of which the globe is composed. In all cases there is a certain dependence upon the parent. This dependence is more brief and slight in some cases, and more durable and intimate in others ; but in no instance with which we are acquainted is there a new animal life produced without some assistance from a parent animal.

When we look at the different classes into which systematic naturalists divide the animal kingdom, we find very remarkable proofs of this. In those which have the least development and exercise of the sensa-

tory or true animal system, we find the egg produced in a very short time, and abandoned by the parent the instant it is deposited. It is true, this egg in the most minute species to which own observation can reach, is always brought forward to a certain stage within the body of the parent, and it is equally true that the parent is in all cases endowed with an instinct, by means of which it places the egg in that situation which is most favourable for its present preservation, its further development, and the obtaining of food by the young animal after it awakens into life. The provision made, and the ingenuity displayed, in many cases of this kind, are indeed truly wonderful; and the reader will find many remarkable instances of them narrated in the general articles ENTOMOLOGY and INSECT, and in various particular articles of that department of the animal kingdom in this work.

Upon this part of the subject it is necessary to exercise a very sound discretion in order to avoid falling into a very serious error; and indeed throughout the whole range of physiology, and it is far from a narrow one, there is more danger of error than in any other department of human study. It may seem strange, but it is nevertheless true, that doctrinal errors in religion are not so injurious, even in a religious point of view, as many of our physiological errors. The physiological error spoils the instrument which we bring to the study of religious truth; and if the instrument is spoiled, no excellence of the materials can make the workmanship good; whereas, if the instrument is sound and perfect, we have means of shifting from the bad material to the good, and so perfecting our work.

The great error into which we are apt to be betrayed upon this subject, and those who betray us into it are often actuated by the purest and most benevolent intentions, is that of ascribing forethought and provisional knowledge to the creatures in thus disposing of their eggs in situations the most favourable for their preservation and development; and by this means a kind of reasoning respecting cause and effect is imputed to the very humblest orders of animated beings. The tendency to do this is so very general, that we can scarcely open a book in which the habits and manners of animals are treated of, without meeting with numerous, fervent, and eloquent expatiations on their sagacity; by which "sagacity" it is invariably meant that the animal so acting *knows what it is about*—pursues a certain course, from a previous conviction that this course is to lead to a particular result.

Now there are only two ways of enabling any being whatever to do this. The first is a perfect knowledge of the future in itself, and without the necessity of any analogy, or the means which can serve as a key to it. If we grant this power with regard to any portion of time, however short, we by necessary consequence grant it for every possible extension of future time, or in other words for all eternity; because if the morrow of this day is known of itself, and without any guidance of analogy, or other experimental clue to what it may bring forth, the to-morrow of next day, and so on without end, must be equally known. But this intuitive knowledge of the future, without any experience of the past, or other means or medium of information, is one of the most characteristic attributes of Godhead; and a being who knows to-morrow, or even next moment in its own unhappened occurrences, must be capable of knowing every jot of the destiny of a world,

or system of worlds, before the same is called into existence. If, therefore, we attribute this kind of knowledge of the future to any animal, whether the perceptive powers of that animal are more or less active and extended—or as we say developed—we, by necessary consequence, make a god of the animal, and thereby destroy our proper understanding and feeling of the God of nature. If we do this, we at once lay the axe to the root of all that is wise and good in our own characters, and with so impure an alloy debasing our understandings, our morality and our religion are nothing more than hypocritical fictions, for the sake of imposing upon the world for the furtherance of our selfish purposes, which, with minds so degraded and debased, can be nothing but gross, sensual, and animal. Thus an error of this kind, though committed with the very best intentions, and expressed in the most proper and even pious language, is virtually a quenching of the immortal spirit within us; and we forfeit the hope of eternal happiness by becoming unworthy of it.

We must, therefore, abandon this notion of the provisional knowledge of those animals, in the depositing of the germs of their young; and when we have done so, the question of "what other kind of knowledge can they have of the future" arises, and demands an answer.

"Coming events cast their shadows before,"

says the wizard to Lochiell, in Campbell's delightful poem. But these are the words of a wizard, a pretender to a portion of that knowledge in himself, which we have shown can be possessed by God only; and though it may be possible that, imbued with the superstitions of his native land, and touched with a live coal from the altar of Apollo, which sublimates and illuminates the fancy high and radiant above the sober, level, and calm light of philosophic thinking, the Child of inspiration may have believed or half believed what he wrote; we must bring him down to that common level, and quench and dim him to that sober light, before we can admit him as evidence. If the coming event does cast a shadow before it, that shadow must tell upon the past; for shadow, as well as light, is not substantive in itself, and therefore it is not revealed to our perception unless it tells upon something, and something substantial if it is to be very apparent. The common shadow in sunlight or moonlight tells on the ground or on the wall, but it does not tell upon the clear atmosphere. In like manner unless the shadow of the future tells upon the experience of the past, it is impossible to trace any knowledge of it; and therefore any being that is not God can have no knowledge of the future, except what it derives by analogy of reasoning from the past, upon the simple and self-evident principle that, like causes operating under like circumstances must produce the same effect at one time as at another.

This is the principle upon which man proceeds in the course of knowledge and the progress of action; but the body of man is merely animal matter, and has no concern whatever in this. Sensation, however keen it may be, and however pleasurable, or however painful, is but for the moment; and it acquires durability as a subject of remembrance only through the operation of the mind, which has the power, though we can but ill explain that power, of recalling our experience of the past, and setting it before us as our means of judgment, and our guide with regard to

the future. The invertebrated animal which deposits the egg in circumstances which appear to us to be chosen with the greatest judgment and knowledge of the future, has no experience of the past to guide her in her operations. All animals of that class may be considered as animals, that is they produce but once, and when the labour of production is over they speedily perish. They also pass through various stages of being before they become sexed animals, and some of them have their duration in that state so brief, that they do not require to feed even once before they have accomplished their purpose, and are gathered to the dust. Under such circumstances it is altogether impossible that they can have any experimental knowledge respecting what will become of their progeny, or whether one substance or situation is more fit for its reception than another. Therefore, though they do place their eggs in the best situations, no sagacity can be attributed to them on this account; and we might as well allege that the misfiring principle and the base, which, when chemically combined, form a salt, have a previous knowledge of the nature of the salt which they form, as that an insect which deposits her single brood of eggs and dies has a knowledge of the future fate of those eggs.

The same principle applies to all animals, not excepting man, in so far as man possesses a material body and is animal. This body has sensation and instincts, as the bodies of other animals have, and as the whole of the senses are perhaps more fully developed in the human body than in that of any other animal, though there are various animals which excel man in the acuteness of single senses, yet we can in no instance take upon us to say that the body is possessed of any knowledge, or that it can recal the past as a guide to the future.

The difficulty of separating the portion of our actions which is bodily or animal from that which is mental renders this a very nice point in the physiology of our own nature, and it is exceedingly difficult for us to perform an analysis of so searching a nature, as to enable us to carry the animal part to the study of other animals wholly divested of the mental part. But if this is not done we spoil the whole by jumbling together elements which in themselves have no natural connexion. We have already stated the main ground of distinction; but, because it is a very important one, and not generally stated in books which treat of this subject, we shall repeat it, earnestly pressing it on the attention of the reader:—the animal principle, whether more or less developed, acts upon matter by suspending for a time the common laws of matter, and assuming to itself, contrary to those laws, the substances which are necessary for the original growth and the subsequent repair of the organisation in which it displays itself. But while it does this it has no knowledge of the matter which it appropriates, or of the laws of matter which it overcomes in this appropriation. It merely performs certain functions, which, according to our knowledge of the subject, are the evidences of its peculiar nature, and it is capable of performing these only for a time. This time is longer or shorter, according to the species; but we are acquainted with no animal which can hold out against the common laws of nature for an unlimited period of time. It appears to be a general arrangement of the whole creation, that the more general in every case shall include and controul

the more particular; and though we cannot in all cases, or correctly in any case, state the precise circumstances which limit the life of an animal to that period which we know to be its ordinary duration, yet as death, by natural decay and without the contingency of disease, is the common lot of all animated beings, if disease does not previously stop their career, we must conclude that this death is the result of causes too general and too powerful for being overcome by the energies of animal life. Hence, though the animal is enabled to overcome and controul the general laws of matter, and apply a certain quantity of matter to its organisation, yet this is a finite power and measurable by time; nor is it unworthy of remark, that, in the same species of animal, an unnatural forcing or stimulating of the power of animal life always abridges its duration; while, on the other hand, a uniform degree of exercise lengthens the life of the animal.

This shortening and lengthening of life by the means we have stated is a perfectly general truth, to which there is no exception; but it is one the statement of which requires a good deal of knowledge and caution before we can pronounce with certainty concerning it. We must know the whole of the functions and actions of life, in order that we may be able to ascertain that they are all affected equally, otherwise the means which we apply in order to procure longevity may actually have the contrary effect.

In contradistinction to what has been stated as the leading characteristic of animal life, that of acting upon matter but not knowing it, the leading characteristic of mind as it exists in man, and we know not of its existence in any other being, is that it knows matter but cannot directly act upon matter. We ought perhaps to exempt from this a certain mysterious reciprocity of action which takes place between the mind and the body, in which they appear mutually to influence each other, both in a pleasurable and in a painful manner. But upon this part of the subject we are unable to speak with much precision; because, though when we come to action in which matter external of the body is affected, or even part of the body itself moved, we can always refer a portion of such action to the body, yet in the commencement of such action as this, namely, in that in which it is induced or begun, it is impossible for us to separate the bodily part from the mental. Thus, for instance, in the act of reading a book, the eye sees a succession of variously formed spots of black on a surface of white paper, and the mind acquires a certain portion of knowledge, different in kind and in value according to the nature of the book, though the markings on the paper, except in the order of their arrangement, may be exactly the same, when the information which the mind receives is of little or no value whatever, or even when it is valueless or pernicious, as when it is of the utmost importance. That there are many mental operations intervening between the bodily perception of the printed letters and the mental understanding of the sense which those letters convey, we have no reason to doubt; but the succession of these operations is so quick that it is impossible for us to take note of them, or to feel any part of the train, except the bodily beginning and the mental ending.

This by the way leads us to another very remarkable distinction between the mental principle and the principle of animal life, and that is the total indepen-

dence of time and space which are evinced by the mental principle; whereas, though the animal principle may be rapid in some cases and slow in others, it always requires some time to produce even the simplest effect; and though the organisation in which it displays itself occupies a very small space in some instances, and a comparatively large space in others, yet it always requires some space. Mind, on the other hand, requires neither time nor space. The swiftest animal—the bird which can fly or the whale which can swim at the rate of more than one hundred miles in the hour, would require at least ten days to circumnavigate the globe, whereas thought, the only exercise of mind which we know, and the most direct evidence which we have of its existence, can go to the remotest star—to every star in the universe, in less time than the twinkling of an eye—in fact, in no time at all. So also, in regard of space, the most minute animal must have a passage opened for it; but mind requires no physical opening—no separation of matter to make room for its march, for thought can pierce through the solid globe, in a nameless fraction of the time which it requires to raise the foot in taking one step across a room.

A clear understanding of the difference between mental action and animal action (for though we speak of the principle of the being in both cases, it is the action alone which comes properly under our cognisance as matter of philosophy) is of the utmost importance at the very commencement of our study of animal physiology. The reason is obvious—almost self-evident indeed. It is impossible for us to avoid making ourselves the standard in all investigations of this kind; and as both reason and revelation teach us that we ourselves are possessed of a mind, or intellectual principle, while all the objects of our senses, and subjects of our physiological considerations, with the exception of our fellow men, are destitute of this intellectual principle, it becomes necessary that we should be able, in as far as such an analysis is possible, to separate it from the standard before we proceed with our comparisons. To do this completely may not be possible in all cases, or even in any one case, but we ought always to bear its existence in mind and make allowance for it. This circumstance alone ought to teach us to be humble, and to beware of dogmatism upon those very recondite points of philosophy, if we have any desire of arriving at the truth.

There is another elementary consideration, which it is necessary that we should well and thoroughly understand, in order to prepare us for entering upon the subject of animal physiology with proper understanding, and to profitable use. This is the distinction between created and finite though intelligent spirit, as it exists in man, and infinite, uncreated, and omniscient spirit, as it can exist in God only. It is not necessary to a right understanding of animal physiology that we should enter into the minutiae of this last doctrine, or that we should show how perfectly consistent the whole tenor of scripture history, and the doctrine of the fall and redemption of the human race, are with the physiology of the entire system of nature, when that physiology is studied in the proper manner. We may mention, however, that those geological and other fancied contradictions of Holy Writ, which have sometimes been brought forward, will, upon examining carefully the characters and even the statements of their authors, invariably be found to have had an origin previous to that study of nature of

which they profess to be consequences, and that they are thus in reality errors and perversions of the study of nature, arising from scepticism produced by earlier causes. The object of the Bible is not to teach man anything of which man can acquire the knowledge without its assistance. God has endowed man with perception, understanding, and judgment, perfectly adequate to the acquiring of every species of natural knowledge which is either pleasurable to the mind or profitable in the arts; and therefore, if God had given man a direct revelation of these things, in addition to this natural capacity of finding them out, man would have been a perfect anomaly in creation, because he would have been the only creature furnished with two distinct and opposite means of arriving at the same results, whereas every thing else in nature is perfect, and, with its single adaptation, the very best fitted for its particular purpose.

We shall suppose, for the sake of the argument, as it is both a strong and a useful one, that the Volume of Inspiration had taught man, in the plainest language, and with the utmost minuteness of detail, every discovery which science has made, and every application of such discoveries to the arts; and having made this supposition, we would bid the reader just ask himself what sort of creature would man have been under these circumstances? Is it not plain that he would have been incapable of appreciating the discoveries, or availing himself of the applications. It is not the mere ultimate discovery, the simple fact that a truth has been arrived at, which draws forth and elevates the human character, and gives that elasticity and importance to the mind which send it bounding onward in the career of philosophical knowledge and useful execution with constantly accelerating speed. It is the labour of arriving at the discovery; and the moment of success, though it be a moment of exultation, is really a pause in the mind's career. When we examine closely the history of human nature, whether in the individual or in the aggregate, we find that the adaptation of knowledge to man, and of man to knowledge, is as beautiful and as perfect as any one of those other countless adaptations which we witness around us. The senses of the body are the primary inlets of all our knowledge of nature; and in proportion as these are exercised in observing, and the relations of the observed facts are traced, we find increased enjoyment and augmented pleasure going hand in hand with what is known; and thus the lot of every man—remorse for crime apart—is nearly as happy as that of any other; that is, the measure of happiness is about equally full to all, though its capacity is very different in different individuals. Imagine it otherwise—or that the whole of natural knowledge, even as it now stands, had been declared to all mankind by direct revelation, and it must at once be perceived that the world would have been a scene of insupportable misery, because the vast quantity of knowledge without object, of desire without gratification, which would have been possessed by a vast majority of mankind, would have been torment not to be borne. But, according to the wise ordinance to man in nature, the craving and the supply come together, and upon the whole bear a very exact ratio of equality. Not that they are mathematically equal, for it is the desire which is the vital or improving principle; and therefore the perfect working of the human system, that is the rational system of man, demands that desire should keep a little a-head, for a reason similar to that upon

which every power or agent throughout nature is always made a little stronger than the average of its work requires.

When we look carefully at the matter, we see therefore that a direct revelation of the knowledge of nature would have been incompatible with the whole of the rest of creation, and destructive of all improvement and happiness in man himself. It would in fact have levelled him with the beasts; and, to use a homely expression, a rational and immortal spirit would have been thrown away upon him. Man, as a created being, is necessarily a finite one, and therefore the knowledge of which he is capable, whether by the immediate exercise of his own powers, or by a supposed direct revelation from Heaven, must necessarily have had a limit under every circumstance which we can possibly imagine. No matter where this limit is taken, for be it wide be it narrow—and admit that within it man possesses by direct revelation from God all that can be known—and to what would such a supposition reduce this knowledge? clearly to nothing else but a set of instincts; for what are the instincts of animals, the habits of plants, the modes of inorganic matter, but so many direct revelations, so many givings forth of that decree of the Creator, which sets its bound to every unreasoning thing which he has created, and says, "Hitherto shalt thou come, but no farther."

Now if natural knowledge, as one science or as many sciences, is thus perfectly incompatible with man as a rational being, it is perfectly evident that the Bible could not, consistently with its being the book of inspiration, communicate this kind of knowledge as its express and original purpose. It is true that it became necessary to extend the line of Bible history backward to the dawn of creation; but the earlier events, those antecedent to what are more essential to the grand purpose of the book, are barely touched on; and as no language could explain in exact terms the manner of the Almighty's acting in creation, the language is of course figurative. The Bible too was delivered to people at different times, and possessing very different degrees of knowledge; and the object of it being clearly that all the revealed portion should be intelligible to the majority of those to whom it was promulgated, it became necessary that, in taking illustrations from the works of nature, which illustrations are indispensable to man's understanding the truths which they illustrate, to take those illustrations in so general a manner as to avoid the temporary and local errors of speculators.

Those who read the book with attention will find that, making allowance for metaphorical language, and for the impossibility of rendering a work with absolute perfection in a translation, there is no ancient book which stands so perfectly free from violations even of the most recent philosophical truths than the oldest book of the Bible. So remarkable is this property, that there is not a single expression in the whole Bible, excepting such as are clearly and obviously metaphorical, which contradicts one single principle that experience has established in the philosophy of nature, how long so ever the expression may have been given to the world before the principle was discovered. This is a very remarkable property of the book, and one which distinguishes it from all books that ever were composed by human ability alone, whether their authors were more or less philosophical. Take any of the systems which

were given to the world before what may be considered as the establishment of the philosophy of nature on the basis of experience, and leaving out of view the mythology with which they may be mixed, it will be found that, upon every point which had not been brought fairly to the test of experience, they are erroneous. It is highly probable too, notwithstanding all that has been done in modern times, that a future age will find the same imperfections in the speculative part of our philosophy. This cannot be avoided, upon the very principle that this philosophy is, by the constitution of man, left to human discovery; and perhaps there is no stronger natural proof of the inspiration of the sacred volume than its perfect avowal of this subject, and never producing error where it would have been inconsistent with its nature to reveal the truth.

These considerations are not generally, at all events they are not habitually introduced into disquisitions on physiology, and yet the subject is very imperfect without them, and unless they are made, the ignorant are very apt to suppose that there is some doubtful ground lying between philosophy and revelation, upon which the investigator of nature is afraid to enter, and the introduction of this suspicion is in itself a serious evil. It were indeed to be desired that the system of nature should be viewed in its connexion, not merely with natural theology, but with the particular revelation of the divine will to man; because if any part is left out, the very fact of leaving it out creates a suspicion that it does not harmonise with the rest.

Perhaps the most perplexing part of the subject, when viewed thus extensively, is the doctrine of the fall of man, and his redemption through Jesus Christ. But when we view this in the sober light of philosophy, we find that it is perfectly consistent with the rest of the system of nature, and we cannot easily imagine how the result could have been otherwise. We have already endeavoured to show that an immediate revelation to man of all that it behoved him to know and to do, would have been inconsistent with his character as a rational being, and have brought him within the class of other animals, over which in all their actions, the laws of nature have complete and absolute power, and which, as all that they do is not only in accordance with the law, but in consequence of it, cannot by possibility violate the law in any one respect. But a creature so tied down would have reason given to it in vain, because that would be furnishing a guide where no guidance were needed, and would therefore be the introduction of something useless into nature, which is contrary to all that we observe of nature, and to all that we know and believe of nature's Author. In order therefore that man might exercise his powers and fill his place in creation, it became necessary to leave his reason to its own exercise; and as the reason of man at any given stage of his being is not only finite in itself, but limited in respect of many parts of that knowledge which is necessary for enabling man to conduct himself in a manner the most conducive to his own advantage, it is morally and philosophically impossible that man could keep, or can keep in the right path by the guidance of his own judgment; because his knowledge never can, in the nature of things, apply equally to all the circumstances or ways in which the future may be affected by the present action. We may say therefore that

the fall, or moral departure of man from the strict tenor of the divine law, was a necessary consequence of the very constitution of man's nature, and that in order to have remained uniformly in perfect accordance with the divine law, he must have been possessed of divine powers, and ceased to be man, which would have been rendering him a totally different creature.

We do not speak of a particular statute, nor a specific act of disobedience on the part of man. There are so many ways in which man can deviate from the law of God, and that law descends so completely to the most minute and momentary portion both of acting and of thinking, that it is impossible to get any name or expression at all descriptive of the whole; and, therefore, upon this, as upon all points in the bible in which it is not possible to express what is meant in direct terms, similitudes must be used, and the meaning of those similitudes gathered from general system. The grand point, however, is, that from the place which man had to occupy in creation, and his perfect adaptation to the occupying of that place, it was quite impossible for him to keep the divine law, or in very many cases to know whether he was keeping it or not.

It is to be distinctly understood that when we speak of man's keeping the divine law, we make not the least allusion to any merit which man would have had in so keeping it, far less of any service that he would have thereby rendered to God. Irrational nature throughout all its departments, inorganic, vegetable, and animal, yields to the divine law the most perfect obedience; but it does not thence follow that there is merit in this obedience, because the hold of the law upon it is too strong for being broken; and it is because the natural law cannot, consistently with the exercise of reason and judgment, have this hold upon a rational being, that man is placed in a situation in which departure from the law is, according to the soundest judgment that we can form, the inevitable consequence.

But, though man is not thus placed under the absolute dominion of the natural law, as compelling him always to think and to act in that manner which shall contribute perfectly to his well being (for this is the meaning of obedience to the divine law); yet he cannot escape from under the power of that law; and if he is not under it for good, in the sense in which we have used the term, he must be under it for evil,—the good in the one case or the evil in the other being wholly to himself, and in no wise affecting either the law or the law giver. It is easy from this to see, that having once deviated from the law in the one form conducive to his perfect good, man was by necessity under the same law in another form not conducive to his greatest good; and that, to return from this state to the former, is even more hopeless than the preservation of the former, hopeless as we have shown that to be; for it has the error already committed, in addition to the liability to commit error anew.

Such, then, is the natural state of man viewed upon principles strictly physiological, and as consistent with the whole system of nature as any one other part of that system is with the rest:—man has departed from the law of his God, he has no power of returning, or of keeping the law for one moment of his life; and, therefore, there is no salvation for him but through one who can partake in the limited understanding of man, and yet be invested with the powers

of Godhead, so that he may bring man back to the law and keep him under it, until the days of man's life as a compound being in this world are numbered. This is the grand mystery of the Christian redemption; upon which it is impossible to enter physiologically; because one element of it is the eternal Son of God, equal with the Father, and therefore infinitely above the reach of all human philosophy. In this world, therefore, the system is of necessity a system of faith; but, independently of the direct evidence of the facts, the perfect consistency of its physiology with the nature of man, places it upon a foundation which nothing but headlong ignorance can dare to assail.

Such as have not been in the habit of connecting this subject with the general system and physiology of the works of God, must not suppose that the few observations we have made are out of place. The subject of religion, viewed in itself, and as between man and his Maker, without reference to human forms, is the most important consideration which the human mind can entertain; and though it is of too sacred a nature for being introduced upon trivial occasions, and too holy for being prostituted as the cloak of hypocrisy, yet it ought never to be omitted when the occasion harmonises with the introduction of it. Having said this, we shall now proceed to notice very briefly one or two of the leading points more immediately connected with animal physiology.

In the former part of this article we have made allusion to the principle and the action of animal life; and leaving these words without explanation, it might, perhaps, be supposed that we alluded to some distinct existence apart from the material substance composing the body of an animal, which that animal possesses. Now nothing is farther from the truth than this. We know nothing of a general animal, which is not any one of the species with which we are acquainted, and yet which includes them all. This was the doctrine of the schoolmen, who in their systems put the wrong end foremost; by supposing that language, according to all their rules and substitutes, was first invented as a complete system, and then adapted to the objects of observation and the subjects of thought. So far from this being the case, these general words are only abridged names for all the particulars to which they apply; and, in the case of any one of them, it is more or less general, according to the extent of knowledge possessed by the party using it. A person who had never seen or heard of any but one species of animal—a horse for example,—would have his general word animal limited to that particular species; and so also if he had never seen or heard of any but one brown horse, his general word would have no further meaning than that single individual. It will be in the recollection of many that when sheep and goats were first introduced to the notice of some of the natives of the South Sea Islands, these natives were very positive in declaring them to be birds: and, simple as this fact is, it serves to show how completely the extent of our knowledge limits the real meaning of our words, however we may pretend to use them.

In this, the proper view of the matter, our word animal extends just as far as our knowledge of what we have resolved to call animation; and when we speak of animal life, we do not use the word life as expressive of some substantive existence which belongs to an animal; we use it as a general name for all the

functions which the animal performs; and then we form our systems, or indices to particular groups and species, upon the modifications of those functions or the results of them. The materials of all this are, however, originally obtained from observations made upon individual animals.

In the case of a single animal, we naturally say that every thing in the appearance, habit, structure, or any thing else of an animal which we can find in no other department of nature, is the result of a function of animal life; but this is nothing but a short expression for its belonging to and being characteristic of an animal, and not of any thing else.

If we attend duly to such precautions in the use of words as we have now stated, we may with safety introduce a nomenclature, and subdivide and arrange the functions of an animal in the same way as we do the different parts of any other branch of knowledge; and though the words which we make use of for such a purpose, are nouns or names, as well as those by which we express substantive existences, we need not on that account confound the realities.

Animal life, then, is the general name for every function which an animal performs; and, of course, it varies along with those functions. The principal functions to which it is most essential to advert in a physiological point of view, are organisation, muscular contraction, nervous agency, and sensation; and upon each of these we shall offer one or two brief remarks.

Organisation is the name for the general process by which new matter is applied to the body of an animal, whether for the general increase of its bulk by growth, or for the repair of any part that may be wasted. This organisation is, however, far from a simple result; on the contrary, it is exceedingly complicated; and as we know the function only from the result, the function must be as complicated. The operations which it performs are in brief as follows: first, the original growth of the body; but this is exceedingly complicated, and is probably very much modified by the other general functions to which we have alluded, and also by the progress of its own development. In the progress of animal growth there is not, in any stage in which we can observe its operation, a mere accumulation of matter upon the rudimental part or germ previously existing. The very matter itself is always a product, and undergoes an operation by which its former aggregation, state, and composition, appear to be completely changed, and a sub-division of all the parts made, probably down to the ultimate atom, before the new compound is formed. This is what we may consider as the initial step of animal organisation, or perhaps we ought to say animalisation, because we must suppose it to take place previous to the formation of any specific organ. We do not, however, find the new matter in the animal structure in that state of its growth which altogether precedes organisation; and therefore the mode of working in this, the most elementary process, must remain one of those mysteries of nature into which we cannot penetrate; and we know not whether the new matter remains in this first animal state during a measurable portion of time, or during an indivisible moment only.

The second stage of the process, though still veiled in great obscurity, leaves traces of its operation in the animal; and therefore, though the working be just as mysterious as formerly, we can see the effects. In the case of the mammalia, we have reason to be-

lieve that, up to the complete organisation of the young one in the maternal uterus of the placental animal, the arterial blood of the mother is the matter which goes to the increase of the fœtus; but even here there is a mysterious application of two surfaces, both apparently imperforate, where the maternal and fœtal parts of the placenta are applied to each other, and while we lose the extremities of the maternal vessels as we approach this singular application of surfaces, which appears to perform the functions of union and separation at one and the same time, we are led to conclude that there is a perfect elemental change in this blood before it passes from the one to the other; and we have a further confirmation of this in the fact that the globules of fœtal blood are not of the same size as those of the blood of full-grown animals of exactly the same species.

In the case of marsupial mammalia, we cannot speak with the same precision as in that of the typical or placental mammalia. In them the uterine gestation is no doubt placental, as well as in the others; though as a placenta, like every other organ, is developed only as it is wanted, it is much more obscure in them. But still when the fœtus is transferred to the marsupium, and freely exposed to the action of the atmosphere, it is still in a very formless and rudimental state, and its future growth, exposed to the action of the air, must be different from that of a fœtus not so exposed.

In both cases, however, the first development of which we are sensible, is a development of organs; and it is well worthy of remark, that those organs appear to be developed very much in the ratio in which they are wanted in the economy of the animal. The theory of development formerly alluded to has been had recourse to in this matter, but with very little effect. It does not appear that there is any good ground for supposing that a single organ of the mammalia changes from its original type, with which it starts even before we can observe it; there is not much greater reason to believe that any one organ originates another, or even that any of the four classes, into which we have said the animal functions can be divided, can in any one of its modifications originate another, although there is not the least doubt that, in their healthiness, and also in their disease, they act and react on each other; so that though no one of those systematic divisions (for they are not natural ones) can be supposed to originate or give life to another, we have every reason to conclude that the morbidity of any one of them can destroy the soundness of each and all of the rest. We have a proof of this in the application of putrid animal matter, and more especially if it be matter of the body of an animal of the same species, to parts which are sound and healthy. The touch of the sound does not heal the diseased, but the touch of the diseased contaminates the sound, and, whether the corrupt matter is general or local, the portion over which corruption triumphs is lost for ever. The pit of the small pox, or the honey-combed scar left by vaccination, when it takes proper effect, is never obliterated in after-life; though much more serious injuries, resulting from mechanical means, are often so changed that hardly a trace of them remains.

These facts tell us little, however, except the extent of our own ignorance upon this subject; and the most careful observations, and the most cautious conjectures, which have been made on the subject, leave it in its original obscurity. The very first movement of

the rudimental animal is really the movement of an organised being, however simple its organisation may be ; and we might perhaps infer this from the fact of there being no new animal originated, without an act of union on the part of animals already existent. While the rudimental animal is still an extenseless thing, or in that state in which it has been called the *punctum saliens*, or starting point, it consists of a containing membrane and contained fluid, which reciprocally act and react upon each other as the first motions of life which it is possible for us to observe ; but even in this state of the mammalia we have no trace of those inferior organisations, through which it is customary with some theorists to suppose that an animal must pass, before it is developed up to the dignity of the mammalia ; for this *punctum saliens*, at the time of its first and feeblest rudimental flutter, is not only an animal but a vertebrated animal ; and not only vertebrated, but clearly and specifically mammalia, and not another class. We cannot speak with so much precision as to how the case stands with the marsupial animals, because they have not been subjected to the same careful examination ; but there is not the slightest doubt but that all the true mammalia are as characteristic in the first movement of their rudiment, and even in their rudiment before it begins to move at all, as they are in the full development of their strength and vigour. On this, as on all other branches of animal physiology, more attention has been paid to man than to any other order of mammalia ; but in so far as they have been examined, the law regarding them appears to be uniform. They are vertebrated animals ; and the spinal column is the first distinctly traceable part of their early organisation. It is impossible to say that this is merely the medullary substance of the spine ; for the probability is, that it contains the rudimental bone, though both the bone and its contents are yet nearly in a fluid state. It is remarkable, however, and calculated to prevent us from doing wrong, if it does not carry us far in the right way, that the spine is developed before the head ; for at its first rudimental appearance, the head, which afterwards increases so much in proportion to the spine, is not perceptibly thicker ; and altogether the development of the spinal column precedes that of the brain, properly so called, though by the time of regular parturition the development of the head has got greatly the advantage.

The only inference which we can with safety draw from this is, that the different organs are developed and come to maturity in that order of succession in which the animal requires them, which is saying little more than that, both in the young and the mature state, the adaptation of the animal to the circumstances in which it is placed, is always the best that we can suppose.

There is evidently an intimate connexion between the early developments of certain parts as compared with others, and the influence which those parts have upon the general organisation of the body ; and perhaps there are none which are in this respect more characteristic or more important than those which determine the specific part that the individual is in future to bear in that most important of all the merely animal functions, the preservation of its race, notwithstanding the successive deaths of generations.

The development (for we may safely use this word in merely speaking of the actual fact of the growth and expansion of an organ which we can trace, and

do not copulate it with any other organ or separate substantive power by which as a substantive existence, we suppose the organ to be developed)—the development of those parts of the body in which the different functions of life display themselves, varies greatly in the different order and genera of the mammalia. Generally speaking, that part of the organisation which carries on what are sometimes termed the vital functions, or those of nutrition, circulation, and respiration, is the first to be perfected ; and we have at least an apparent reason for this in their necessity to the development of the rest. The organs of locomotion, and of those other motions which are usually called voluntary, or which the animal appears to have controul over in suspending or continuing at its pleasure (at least within certain limits), vary perhaps more in the degree of their development at the time of birth than any of the others. This might be expected to vary in proportion to the nature of the food of the animal, and the degree of ease with which this food can be reached and taken possession of. Thus a grazing animal which nips the tender leaves of the grassy sward that supports it, can find its food at a very early age, because the finding of such food requires comparatively little labour or strength, or what we call sagacity. An animal, on the other hand, whose food requires greater exertion and effort, and has to be lain in wait for, or hunted down, or taken by force in any way, and against resistance, requires a greater degree of development before it is able to depend on its own resources. We accordingly find that such animals are fed as well as suckled by their parents, and that in the young state they are gentle and playful, and do not acquire their predatory dispositions until the weapons, and the muscular structure necessary for the working of those weapons, have acquired the proper tone.

There are differences in different species, for which the physiological causes cannot perhaps be assigned in a manner altogether satisfactory. But still it is a general law, the deviations from which appear to be perfectly explainable in so far as we know the facts, that the length of time requisite for bringing the animal to perfect maturity, bears a pretty constant proportion to the resources which the full grown animal is to possess, and the necessity which it has for those resources. The human race furnish perhaps the most remarkable instance of this. Human beings are longer in arriving at the full development and exercise of their bodily powers than any other animals, even though the lives of those animals are of longer duration than the life of man ; and when in addition to the bodily powers we take the mental sagacity, we find that this goes on increasing, even after the decay of the others is far advanced, which, by the way, is a strong proof that those powers have quite a different origin and depend on a different agency from the mere powers of the body. In this last respect we cannot find an exactly parallel case in the rest of creation, because there is no mind there ; and in our virtual analysis of human nature, it is difficult for us in all cases to separate the mental portion from the bodily ; but in as far as this can be done, we have the analogy continued in man, who, as being the animal of most varied resources, viewing him merely as an animal, is also the one of most tardy development. The same holds good in even the two sexes of the human race. As society is constructed and conducted in all

countries, and we must conclude from the universality of the fact, that there must be something natural in it, the male is, taken upon the average, though there are many individual exceptions, possessed of much more resource than the female, and we find that the female comes first to maturity.

But it were idle to follow the details of a subject, the grand connecting portion of which is beyond our reach; and, therefore, though we cannot but admire the process of growth in animals, and the adaptation of the various parts of that process to the necessities and habits of different animals, yet the commencement, the rationale, and the principle of this process lie beyond the reach of our inquiries; and, whether we address ourselves to the living animal, or dissect and analyse the different parts and structures of the dead one, we equally fail in our attempts to arrive at any thing which we can distinctly consider as life, or the principle of life; we know life as it displays itself in the living animal, but beyond this we are wholly in the dark concerning it.

Nor are we better with regard to the particular process by which individual portions of this work of animalisation is carried on, whether in the growth of the animal body or in its repair. This is the second branch of the general doctrine of organisation; and the common name of secretion which it has received is of itself enough to show that we know very little about it. There is no doubt that the organic changes constantly going on in the animal body are exceedingly numerous; and that though we give the name of secretions to a certain number of the permanent products of those changes, yet there are others of so evanescent a nature as that they leave no trace in the structure of the animal, but vanish with the action of which they appear to form part. So far all the named secretions, or rather perhaps the preparations for them, appear to be mechanical, and whether the matter of the secretion is taken directly from the general mass of the blood, or consists of other matters, the process is to some extent mechanical. As the secreting apparatus is approached, there is a subdivision of the conducting vessels into parts still more and more minute; and it has been found that if a more dense and a more subtle fluid be injected into those vessels by mechanical force, the subtle one will extend further, and into more minute ramifications, than the other; but in no instance has the seat of secretion itself, that in which a distinctly new substance is produced, been reached by any effort of human ingenuity. This matter of secretion in the body of an animal, whatever the product of the secretory process may be, brings us always to a difficulty of the same kind as the original production of animal matter, and we have no more means of solving the difficulty in the one case than in the other. We can follow both to the extreme limit of the eye and the microscope, but at this limit they take farewell of us, and veil themselves in obscurity without vanishing from existence. We know that the ramification of the conducting vessels into diameters still smaller and smaller at every branch, must mechanically subdivide the blood or other fluid contained in them into parts still more and more minute, as the ramifications are further and further carried on; and we are also led to suppose that in proportion as this division becomes more minute, the action between the internal surfaces of the containing vessels and the fluids which they contain must be greatly increased, upon the principle

that the contents of vessels are as the square roots of their surfaces, or the surfaces or the squares of the contents. We have also some reason to believe that all living action, whether animal or vegetable, is ultimately reducible to the action of surfaces upon each other; for this is really the law which is followed in all the analogous kinds of action, and we find it in every rudimental case in which we can observe action either in animals or in vegetables. All this, however, is but little; and when we have reached this length, we leave the rationale of secretion as we are forced to do that of life and growth—very nearly where we found it. We must, therefore, however desirable it might be to obtain more intimate knowledge of the subject, leave it and proceed to the others.

Muscular contraction is the one which naturally follows next in order; and it is probable that in the growth of animals, it, to some extent or other, is the first modification of what we call the general organising, or rudimental production of an animal. So far as is known, this function is peculiar to animal matter, most ordinarily resident in the muscles, but still transmissible from one part of the body to another, even though there is no muscular connexion between them. This function, or rather the power which is understood to give origin to this function, has been called *irritability*, and a variety of other names; but it is like all the other powers for specific purposes which have been attributed to animal bodies, or to different parts of them—we know nothing of it as a power, we merely observe certain effects; and we use this name power, or any of the particular names, for the purpose of enabling us to speak about their unknown causes, by which again is meant those states of the animal body, which take place before we can begin our observation of it, and which of we of course can with certainty know nothing. It was long confounded with what is called nervous action; though subsequent experience has shown that though combined in producing certain joint effects, they are yet distinct and separate, both in their nature, and in the parts or structures of this animal body in which they peculiarly reside.

It is of little consequence what name we give to this power, so that we understand the effects of the power itself; but it is of the utmost consequence that we should understand these, and how they differ from each other in different animals, and under different kinds of excitement; because this is a part of the subject essential to the proper explaining of very much of the action of animals. Haller was the first who gave even a tolerable account of the phenomena of this power; and as he used irritability as the discriminating name for it, it is not worth while to alter the name, if we rightly understand the sense in which it is used. It is not irritability in the common sense of the term, in which it means anything indiscriminately which gives pain or annoyance, which must be understood of this irritability of the muscles; it is the fact of a healthy muscle shortening in length, and at the same time swelling out in thickness, when certain stimuli are applied to it.

What those stimuli are, and whether they are the same, in all natural cases, in the same muscles of the same animal, we have no means of ascertaining; and there is as much difference among physiologists respecting the ultimate structure of muscles. They are all composed of fibres as already stated; but how those fibres contract is a point upon which there exists

no precise information, and therefore the theoretical explanations which have been from time to time attempted, have generally borrowed their foundation from the particular department of science which happened to be most fashionable at the time of their invention. Among the oldest of those theories, or rather hypotheses, for none of them amounts to a theory, is that of Borelli, who describes the muscles as consisting of rhomboidal vesicles, which are empty and stretched in length when the muscle is relaxed, but filled with a nervous fluid, which enlarges their diameter and increases their length when the muscle contracts. The principal objection to this hypothesis lies in the facts, that we are acquainted with no nervous fluid which circulates, and could be injected into muscular vesicles by any mechanical power; that there is no structure in which such a power could reside, unless we supposed the contractility of the muscle to be transferred to it, which would be no explanation, and that muscles retain this power after all nervous connexion with them is broken off. That action, and very powerful action, mechanical in its effects, is produced by the contraction of muscles we cannot deny, for we have instances of it before us every day, and that the exercise of this action is intimately connected with the general energy of all the functions of the animal is also true; but neither the one nor the other of these, nor any other hypothesis, mechanical or chemical, throws any light whatever upon the real cause in which muscular motion originates.

In the mammalia, the muscles are more copiously supplied with blood-vessels than any other parts which are to be considered simply as working structures, and not engaged in secretion, or in specific action upon the blood itself; and a degree of heat is always excited by violent muscular action; but it does not appear that either of these is connected with muscular irritability. For in other animals, which have the circulation far slower, as for instance in reptiles, the irritability of the muscles is much greater, and they can be excited not only after the circulation has been stopped, but after the limb containing them has been separated from the body.

Observation and experience would thus lead us to suppose that muscular irritability is an antagonist to the stimulus of the blood, to that of the nervous agency, whatever that may be; and generally speaking to all other agents, external or internal of the system, which can have an influence upon muscle; and that therefore the contractility, in which way soever it originates, is a power perfectly *sui generis*, and explainable in or by nothing but muscles themselves. When the muscles serve for the purposes of propelling the contents of vessels, we may generally suppose that the contents are the stimuli of these vessels; and we have pretty convincing evidence of this in the fact that the introduction of artificial stimulants, even in small quantities will increase the excitement, while sedatives have a contrary effect. The stimulus of arterial blood appears to be a powerful one, and one which is essential to the excitement of muscular action, especially in the mammalia. Dr. Fordyce notices a fact, which shows that the power of muscular contraction can greatly exceed that of the stimulus by which it is excited. Upon introducing a needle into the ventricle of a very recent heart, and touching the inner surface very gently, the ventricle contracted with so much force, as to force

the needle deep into its surface. This is farther illustrated by the well known fact, that animals, especially when in a state of excitement, run forcibly upon any weapon which pricks them ever so slightly, and in this way horses, and also men, run upon weapons in battle to their certain destruction.

Every possible component part of muscular substance, and every agent which appears to affect the action of muscles, have been investigated with the utmost care; but though it has been repeatedly shown that many, if not all of these, are necessary to the production of muscular action, it has not been proved that any one of them, or even the whole of them taken jointly, are the real sources of that action. It is unnecessary, therefore, to follow them further into the details, although to profound physiologists those details are of the utmost value.

A power directly the opposite of that of contracting has sometimes been attributed to muscles; but it does not appear that there is any reality in the supposition, and indeed it is opposed by the whole analogies of the case. We never find a contracting muscle which tends to draw a part of an animal to any distance in one direction, which is not accompanied by a counteracting power which can bring it back again, or move it in the opposite direction. In the limbs of the mammalia, and in all parts of their bodies which are concerned in their external motions, there are antagonist muscles set against each other as it were; but if the object is merely to bring back a part to a certain position, it is not necessary that the antagonist which effects this when the muscular action is over should be a muscle. An elastic ligament attendant, or even the cellular tissue, may effect this purpose, and there is little doubt that the cellular membrane which sheaths the fibres and fasciculi of the muscles tends to restore them to their form in repose, when the contracting action of the muscular fibres, properly so called, is at an end. Many membranes in the living animal possess a power of contracting in every dimension, at least in extent of surface, under the operation of proper stimuli. This is called corrugation or crumpling up, and it enters to a considerable extent into the structure of those animals which have soft parts. In the mammalia, however, which have the skeleton more perfect, and the muscular system more distributed than any of the other animals, muscular irritability is to be regarded as the grand source of motion, and the only one to which it is necessary to have much recourse in treating of such actions of those animals as are necessary for understanding their habits and adaptations in a popular way.

The action of the nerves is the next department of the physiology of the warm-blooded animal; and as those nerves in the central part of their system are protected with much more care than any of the other parts, and are much more developed in the mammalia than in animals possessing less sagacity and resource, it is natural to conclude that they form a very important portion of the structure, and one which must not be overlooked. This is, however, a branch of the subject which is exceedingly difficult in itself, and to the consideration of which we are in great danger of bringing some prejudices, or at all events some mistakes, along with us to the contemplation of it. In all the more complicated phenomena of the living animal, particularly those of sensation, and of action as consequent upon sensation, we are in con-

actual danger of carrying the matter further than animal physiology in the proper view of it will warrant. This is unavoidable, from the circumstance of our naturally taking ourselves as the standard of judgment in these cases; and from there being a mental process in addition to the merely animal one, in every case in which a *known* impression is made upon our senses. There may be slight momentary affections of the body as matter, which pass away without mental cognizance, just as there are mental impressions once known which may never again return in those suggestions to which we give the name of remembrings; but in every case, where the impression on the sense is sufficiently powerful and continued, for the mind taking note and forming a judgment concerning it, there is an element between the initial impression on the sense and the final thought, whether that thought does or does not ripen into action, which can belong to no other animal. This mental part of the succession is inferred rather than originally felt even by ourselves, and therefore the separation of it is in all cases exceedingly difficult.

There is another source of difficulty;—we can say very little of the mode of action in nerves, because there is nothing to which we can compare their structure. It does not appear that there is any circulation in it; and it does not appear to be a substance calculated for transmitting any powerful kind of action of a mechanical or chemical nature. The most careful examiners are not agreed as to the structure of nervous matter, and even though that were made out, it would not explain nervous action. That it is a means for the very rapid production of animal action, we have no reason to doubt; and the analogy would lead us to suppose that that which it resembles the most, though we cannot say that they are identical or even alike, is that display of action to which we give the name of galvanic electricity. We know that this electricity is one of the most powerful solvents that can be applied in the arts; and as the arts cannot, of course, introduce a principle, or even a mode of action, further than as it depends on the use of apparatus, we may naturally suppose that this mode of action enters very largely into the operations of nature; and more especially in the more delicate functions of life in the mammalia as the most highly developed of animals. It is known that the division of nerves, connected with organs of secretion, impairs the functions of those organs, though the way in which this takes place is not so clear a matter. There is one other analogy which would lead us to conclude that there is such a connexion between the excitement of nervous action and that of galvanic electricity as has been stated: for those fishes, such as the torpedo and the gymnotus which have electric organs, which resemble galvanic batteries, and are capable of giving severe shocks, have always those organs very copiously supplied with nerves. We must be on our guard, however, against laying too much stress upon this analogy, or supposing that our galvanic batteries can point out to us how such batteries are worked by nature; because too much credulity on this subject, or too much of some other means of bringing it forward, has occasionally introduced much electrical quackery into the art of pretended medicine.

That the excitability of the nerves, even in man, is not necessarily connected with or dependent upon sensation, in the common meaning of the term, to say nothing of mind, is proved by many direct experi-

ments; and indeed the actual existence of life does not appear to be absolutely essential to the one any more than to the other; for it may be called into action not only after the part has lost what is properly termed sensibility, but after it is divided from the body. A certain condition of the organs in which it is excited, as well as a certain composition in those organs, appears to be necessary to the production of this excitement; and in the mammalia and other warm-blooded animals there must be a connexion of nervous substance, freedom to act, and a continued supply of blood; but from some experiments detailed by Dr. Philip and Mr. Brodie, in the *Philosophical Transactions* for 1822, it appears that absolute continuity in the nervous substance is not essential; for when the ends of a divided nerve are brought very near to each other, the communication by means of that nerve is not wholly destroyed. The whole doctrine of the nerves and their modes of action is, however, very imperfectly known; and what is known is not well adapted for popular explanation.

Sensation, the last function of the animal system to which we deem it necessary to advert, is so closely connected with nervous excitement, and the obscurities of the one are so much involved in those of the other, that we cannot speak confidently beyond what we feel in ourselves, and there are doubts and difficulties even there. The word too has been used in different senses, and in some of them with great latitude of expression, though in other instances it has been narrowed beyond its proper meaning.

Generally speaking sensation, or rather sensibility, for sensibility is the function and sensation the exercise of the function, is applied to the quality of receiving impressions from objects or causes external of the organ immediately impressed. Those impressions are very different in their results, even in the same animal, or part of an animal. They may be pleasurable, they may be painful, or they may be decidedly neither the one nor the other, but merely what we may term *informatory*, and their effect may be to produce, terminate, or suspend the actions of the body both external and internal.

Sensation, in this view of it, extends almost to every part of the animal system; for if the part is considered as not immediately capable of receiving an impression itself, it always can transmit the impression to some other part which can. In a perfectly healthy state of the body, and in undisturbed repose, as when it is in dreamless sleep, it is all insensible to slight impressions; and if the sleep is very profound, it may be seriously injured without sensation till the injury is done. In disturbed sleep, which is broken by dreams, there is always some remnant of sensation, arising from a disturbing cause; and thus dreaming is not, in its primary state, an affection of the mind even in man; for, from the very nature of the mind, it cannot sleep, and in those animals with which we are familiar in their sleeping hours, there are evidences of dreaming as well as there are in man, though we are as ignorant of the nature of their dreams, or of how these differ from our own, as we are of the difference between sensation accompanied by mental action and sensation not so accompanied. Various diseased conditions of different parts of the body will also bring very acute sensation into parts which do not possess it when in their natural state of health, as for instance tendons, ligaments, bones, and even fatty substances may experience most acute pain from

diseased action. Irritation or pressure will produce these results: and this would lead us to conclude that all sensation is ultimately resolvable into some suspension or change of the general motions or actions which are continually going on in the very complicated structure of the animal; and that the sensation, whether its immediate cause is external or internal, is extensive in proportion to the extent of this resistance. We have a very clear proof of this in those cases in which both men and animals are panic-struck by appearances or impressions of any kind upon the senses, which are not only not dangerous in themselves, but which under another previous state of the system would be regarded with perfect indifference, and probably with pleasure.

The most interesting, but at the same time the most difficult, portion of this branch of physiology is that which treats of sensations that lead to action in the animal. In the mammalia, and in other animals not endowed with mind, the reciprocating principle, which as it were transfers the sensation to action, is called an instinct, and this instinctive mode of action prevails also in man, and the form of it is put on after long habit, in many cases of which the first instances are the undoubted results of mental inquiry and determination, upon judgment formed according to the evidence. From the difficulty already mentioned as arising from our inability so to analyse our sensations, or rather the impressions we receive, into the animal part and the mental part, and this additional difficulty produced by the merging of processes once mental, in habits merely animal or little else, render this an almost inexplicable part of animal physiology. Many hypotheses have been formed for the purpose of explaining it; and as in these hypotheses structures have been endowed with gratuitous or imaginary functions to make them agree with the phenomena, there is some plausibility in every hypothesis of this kind, but it is impossible to say that there is philosophic truth in any of them. One of the most commonly received of these hypotheses has been that of two sets of nerves, one of them originating in the brain and its spinal continuation, and ramifying thence to all the surfaces and terminal parts of the body, where their extremities, furnished with certain structural apparatus, such as papillæ for touching and tasting, and more complicated structures for hearing and seeing, stand as sentinels there, and send word of whatever is going on to the great central mass of nervous matter, which, according to the hypothesis, is the sensorium or seat of instinct in the irrational animal, and of instinct and mind jointly in man. It is to be understood that this is perfectly gratuitous, or that at all events the alleged functions have been invented or shapen so as to suit the phenomena which are said to arise from their exercise; but there is a business-like mechanical detail about it, and therefore it has never been without numerous and devoted adherents.

But before any novice takes it up dogmatically, he would do well to consider that we are, and are likely for ever to remain, in perfect ignorance of the principle which moves the smallest fibre of the most delicate muscle in its contraction; and as this sensorium is a structure of many "stories," resting upon the supposed knowledge of this power of action in the muscular fibres as its very first foundation, it cannot surely have much more philosophical stability than that upon which it is presumed to rest.

It may not be amiss to notice the second or reversed part of this supposed communication, between the nerves which are ramified through the organs more immediately concerned in action and the sensorium. The course is the opposite of the former, according to the hypothesis, but not necessarily by the same means, as the perception and the action may not be performed by the same parts. It may, for instance, be the sight of a hare by a greyhound or other dog, and the following of that hare in the chace; or it may be any other sensation, and any other action; but there is always understood to be an informing of the sensorium, which is not supposed to have in itself any direct knowledge of the external world, or even of the internal structure or action of the body of the animal; but which nevertheless always decides whether action shall or shall not follow the deliberation on the evidence, and in what manner and to what extent the action shall be carried on.

All this is done too by means of organisation in the sensorium; and the different parts of this organisation affect the result differently, according to their different degrees of development and consequent power. Thus a village cur, with short bandy legs and a wriggling body, sees a hare as well as the greyhound did. His organ of acquisitiveness is instantly roused, and off he waddles, losing on the hare at every step, because his organs of locomotion will not obey the full bent of the acquisitive organ. Thus, in him at least, we have the effort of the sensorium foiled by the stubborn resistance of the external organs. Innumerable cases of a similar nature might be mentioned, in which it is impossible to impute the success or failure of the action, or even the commencement of it, to any thing but the general structure and present circumstances of the animal, and this casts much doubt upon the whole hypothesis.

But the whole case as it applies to the mammalia, and by necessary consequence to all the lower classes of animals, must necessarily be explained upon animal principles alone, without the slightest reference to any thing mental; and this notion of a sensorium, consisting of a certain portion of the animal's organisation, which receives the impressions of the senses either from the local organs of particular named senses, or from the general sensibility of the animal; and then, after duly understanding the impression so brought, puts the organs of action in motion, according as the result of its judgment may be, is really endowing the animal with an intellectual principle or mind, whatever name may be given to it.

The author of this article does not believe that the source of action in animals, even of that kind which is consequent to sense or perception, can be shown to have its seat in the brain any more than in other parts of the structure. That the brain is the central mass of the nervous system, and that it supplies nerves to the organs of the allocated senses, which are, for convenience of use, situated in the head of all the mammalia, is perfectly true; and it is equally true, though the particulars are much more obscure, that a healthy state of the nerves is necessary in order to make those organs perform their functions properly. This, however, proves nothing as to any exclusive possession of the faculty of sensation, and of the stimulus to action in the nerves; for a healthy state of the blood vessels, and even of the lymphatics, is just as essential to the proper functions of the organs of the senses as a healthy state of the nerves. We have an instance of

this is the fact that when the vessels immediately surrounding the eye are relaxed and distended with lymph, in consequence of long and severe exercise of the organ, the sight becomes dim, the eye will not adjust itself, and small objects are seen double. One of the most immediate remedies for this is the application of a sponge soaked in a solution of salt; and this acts by drying up and giving tone to the parts, so that the delicate muscles, which adapt the form of the eye so nicely to its purpose, are again enabled to act. We know that salt applied to a muscle will make it contract, whether the nerves of that muscle are or are not removed; and therefore this application of salt, as a tonic to the region of the eye, obviously gives an artificial power of contraction to those muscles which had been exhausted and relaxed by excessive use.

From this, and from a countless number of other instances which could be enumerated, it appears that the impressions made by objects of sensation, are really addressed to the muscles, and not to the brain through the nerves, however necessary a healthy state of the nervous system may be to the proper performance of the functions of the muscles, in sensation as well as in action. Indeed it is difficult to understand how there can be any pause or medium between sensation and action in an animal which proceeds upon instinct, and not upon the judgment of experience, which in all cases requires deliberation. In man, where there is an intellectual principle, to make the comparison and draw the conclusion, we must admit that sensual perception, intellectual judgment and decision, and bodily action, are the three parts of the compound process, when that process is complete. But it is probable that, even in man, the operation of the middle part may sometimes be left out, and man may play the animal; and we have stated already that there are other cases in which from habit the mental part of the process is unheeded.

But when we return to the animal, and consider its case in comparison with the complete case in man, which is always our natural standard in these matters, we do not see how there can be any middle part of the process in the animal, unless we attribute this part to something mental; and as the want of the grand characteristic of mind in all mammalia, even the most sagacious—the total absence of any tendency to communicate experimental knowledge among themselves, or to hand it down from generation to generation, each generation adding its part to the general mass, forbids us from coming to the conclusion that any of them can possibly be possessed of mind, we are driven between the horns of a dilemma, and cannot avoid concluding either that the animals are possessed of mental and therefore immortal principles, or that the entire nature of man is material, and lost for ever as regards the individual, in the dissolution of death and the decomposition of the body, in the very same manner as in the other animals. But either of these conclusions is so contrary to the evidence afforded by nature generally, and by the physiological examination of man, that, leaving revelation out of the question, we cannot entertain either, without outgaging every principle of sound philosophy.

We have direct proofs in some animals, that the power of originating action is not altogether seated in or directed by that portion of the nervous mass which occupies the skull. Many reptiles can move about after the head is separated, or the spinal marrow

divided, though their motions are not so regular as when entire; but this is the case in every mutilation of an animal, and therefore, when an injury is done, we are always warranted to suppose, that if it affects any of the general systems of the body, no matter which, it affects the compound structure of the body, in its functions as a whole, to the very same extent. Many readers must have heard of the archery of the emperor Commodus in the circus. He had his arrows made with a cutting edge, and these he discharged at ostriches driven across the arena, so as to cut off their heads when about mid-way, and they ran headless to the end of their journey. The same has been observed in many other birds, and also in the lower classes of vertebrated animals. In the mammalia the separation of the head, or the division of the spinal marrow, is attended with much more immediate effects, for the animal is instantly thrown into a state of complete stupor; but still there are some instances in the smaller animals of this stupor wearing off after a little, and the animal making efforts to reach the wound in the neck with the hind feet, so as to alleviate the pain, which animals that have much action of the feet always attempt to do, by bringing the foot to the wounded part if they can reach it.

From all the evidence which we can collect, indeed, it appears that there is no pause, no intervention of a middle process between the sensation and the action to which the sensation leads. But it does not follow from this, that sensation in animals should in all cases be continued into action, because every animal requires some excitement, and even the same animal requires more excitement in some states than in others. Indeed, it is this necessary connexion between the degree of excitement and the result, as constituting only one state of the animal, which leads us to call the actions of animals instinctive, and which gives them a certainty and a regularity which those of reasoning man cannot by possibility possess. The animal is not a machine in our sense of the word, that is to say, the working of its system is not mechanical, or chemical, or even compounded of the two, but it is animal, or peculiar to this particular form of created being; but notwithstanding this, inanimate and inorganic matter is not more obedient, or more instantly obedient, to the laws of physics and chemistry than every animal is to the laws of animal life. Those laws vary with generic and specific differences, and circumstances vary them, though less extensively, in the individual; and we cannot account for the original differences of species; but our ignorance of the same differences is as great in the case of inanimate substances, and our ignorance ought certainly not to be made a ground of argument.

To enter into any details of the physiology of mind, farther than the general distinction between it and animal action, which has been already hinted at, would be inconsistent with the nature of this article; but if it is once established that the nervous system, as well as the systems of circulation, nourishment, motion, and all the others which have different organs in the animal structure, are constituent parts of that structure, and that the proper efficacy of each in the performance of its functions, requires the healthiness of the others, just as much as that of itself; then it cannot be pretended that any one system singly can be the seat of voluntary action, or of the cause and stimulus of voluntary action, when that action requires the co-operation of the whole. The more vigorous,

active, and, as we say, intelligent the animal is, the more completely are the parts of its system developed; and this holds in the case of the human body as well as in the bodies of all animals. It would therefore be inconsistent alike with general reasoning and with the facts, to suppose that there is any difference in kind between the nervous system of man, and that of the other mammalia; though as the senses, taking them altogether, are more uniformly strong and more constant in their exercise in man than in the others, for this reason, and apparently for this reason alone, the brain in man is much more developed; and in proportion as we find the senses more feeble in some of their number, and more partial in their general exercise, we find the brain smaller. But when we attempt to make the brain the means of explaining any of the phenomena of mind we are still more in the dark, than when we endeavour to make it the means of explaining the phenomena of sensation and action in animals. In every case where the impression in sensation or the exertion in action is sufficiently strong, we find that it extends to the whole body of the animal, and that the agitation of the parts most remote from those which are immediately affected in sensation or exerted in action, is in some cases as great as that of those parts themselves.

The only rational conclusion to which we can come in animal physiology, notwithstanding the countless hypotheses which have been broached upon the subject, is that we can have no abstract notion of animal life, and therefore no means of actually separating it into distinct functions, the influence of one of which upon another can be at all understood. This term "animal life," is merely a name, by means of which we generalise all the phenomena of animals, just as "matter" is merely a name, by which we generalise all substantive existences which are in any way palpable to our senses. In both cases, the phenomena alone constitute the knowledge, and our general names are merely short modes of expression, answering to which there are no real existences. In the animal, however, we can carry our observation of phenomena much farther, and more in a train of succession, than we can do in the case of inanimate matter; and therefore the animal is by far the more instructive study of the two. It is more sensitive to external stimuli, arising from difference of situation, difference of season, difference of weather, and every thing else of general nature which can have difference at different times or in different places; and besides those obediences to external stimuli, there are internal stimuli in an animal, arising from those necessities which are inseparable from a material organisation, in continual action in some of its parts, and therefore requiring continual repair, the means of which are contained in itself, though the materials are derived from without, and taken in quantity proportionate to the waste of the animal, and the fitness of the alimentary substances for being applied to the purposes of growth or of repair.

There are many minor points in the physiology of the mammalia as the highest or most typical class in the animal kingdom; but as there are, generally speaking, adaptations to the situation and circumstances in which the animals are placed, they belong to the details of the several orders and minor divisions of the mammalia, rather than to the general functions of the class. We shall therefore proceed to the next branch of our general sketch of the order, namely,

the modifications of their external action, and the organs employed in that action, so as to suit them to the places and the purposes for which they are appointed on the earth. Feeding is the grand stimulus to action, at least to general action, during the whole of every season of activity in all the mammalia; and as the food consists of a vast number of substances—of plants, from the lichen which feeds the rein deer in the polar latitudes, to the leaves and twigs of the most lofty trees in tropical countries, and of the flesh of every animal, from the small insect which is picked up by the viscid matter on the projectile tongue of an insectivorous animal of the humblest class, to that of the elephant itself—a knowledge of the food of the mammalia requires at least a general knowledge of the vegetable and animal productions of all parts of the world; and also of the situations in which they are to be found, and the most ready means of getting at them; and thus the study of the mammalia, when pursued in the proper manner, is a strong incitement, and very soon becomes a clear and readily consulted index, to natural history generally.

The feeding of animals, from the arousing of the animal by hunger, and its quitting the place of its repose to go in quest of its food, till the food is taken, prepared for the process of digestion by the mouth, and the animal again relapses into a state of repose, until fresh hunger shall excite it to a new exertion, is conveniently divided into three successive parts. *Locomotion*, or the conveying of the animal to the place where the food is to be found; *prehension* or the taking of the food, whether vegetable or animal, wholly within the power of the animal; and *mastication*, or the action of the mouth in preparing the food for the stomach. Our business in a general sketch is to notice the leading diversities of the organs by which these operations are performed, and the adaptation thence traceable both to the place of the animal in nature, and to its general structure. We shall very briefly glance at each of these in a separate section.

III. ORGANS OF LOCOMOTION.—The several kinds of locomotion exercised by the mammalia, though very many in their minor shades of distinction, may be reduced to the general heads of climbing, flying, running, leaping, and swimming; and as these are performed by means of the feet, there will of course be the same distribution of the feet into general heads; only, as each operation indicated by the general name is performed in various ways by different animals; and as, in addition to this, the feet, more especially the fore feet, have often other functions to perform; this circumstance will increase the number of modifications. Among these, the organ of flying is the one which performs its operation the worst; because the general structure of the body, and especially the articulation of the spine, the form of the sternum, and the absence of coracoid bones under the flying extremity, how much soever it may be developed, render it a very ungainly organ of flight as compared with the wing of a bird.

The organs of flight, and also those organs which are adapted for swimming and not for walking or any motion upon the land, are so anomalous to what may be considered as the true typical form of the mammalia, that they are worthy of a separate notice; though in their physiology they are as decidedly mammalia as any of the rest, and though in respect of their feeding they ought to come under different

classes, as a few of both live upon vegetables, though by far the greater number are animal feeders. Considering these circumstances, we shall notice their organs of motion separately from the rest, inasmuch, as all the other mammalia make the successive steps of their advances from solid supports, whether the length of the step be longer or shorter, and whether it be or be not prolonged by membranes which, like parachutes, take hold in the air, and prevent them from having so much downward motion as the natural gravitation of the mass of their bodies would give them.

Organs of flying.—We shall, in our summary of the systematic arrangement of mammalia, mention the characters of the different groups which make up the numerous and widely distributed family of *chiropterus*, or volant mammalia; and therefore, as our object in the mean time is to point out those deviations from the typical structure, as already described in that of the human body, we shall confine our observations to the bats, which are by far the most characteristic, and the ones which are most efficient in aerial motion, and least so in progressive motion along the ground. Indeed they are less effective upon the ground than any of the air birds, the swifts hardly excepted, which are rarely seen but on the wing, or clinging to the sides of high rocks and lofty towers in the same manner, though not by exactly the same kind of organisation, as the bats cling to the internal surface of caves, the undersides of the branches of shadowy trees, and other objects by which, as they are nocturnal animals, they may be protected from the direct light and heat of the sun, which no nocturnal animal can well endure. It will facilitate our explanation more if we introduce the skeleton of a bat, than if we were to give figures in detail of those parts which contribute to the peculiar action of these animals; because, as the form and articulations of the skeleton determine the general motions, it is not difficult for the imagination of any reader who is tolerably acquainted with the organisation of any one of the mammalia to understand any other as clothed with soft parts, answering to the peculiarities of the skeleton. The figure represents the skeleton of a bat.

The parts of the skeleton here, that is, the grand divisions of head, trunk, and members, are the same in number and general position with regard to each other as they are in man; but they differ greatly in their form, the development of their different parts

and in the details of the extremities. On examining the anterior extremities, which we shall call the wings, though in every respect they differ from the wings of birds, it will be found that they differ greatly from those of mammalia, which have not the power of flight, whether the principal action of the fore extremities in these be progressive motion or any thing else. It will be seen that the scapula or blade-bone is very large, which affords it a firm embedment among the muscles on the back, and that the clavicle which forms the reacting bone, and keeps asunder the two sockets which receive the heads of the humeri or arm bones is also very strong for the general mass of the skeleton. The coracoid bone, as already noticed, is wanting, however, and the clavicles extend directly to the sternum and bear upon it, instead of forming a distinct arch or furcal bone, as in birds. The support of the shoulder joint is thus very strong for the size and strength of the animal; but it has not the same steadiness as the shoulder joint of a bird, which rests upon a tripod, and as the middle bone of that tripod, the coracoid, abuts firmly on the sternum, while the others are comparatively free, the one in its arch, consisting of the two lateral portions united, and the other in its embedment entirely among flesh; the sternum is the bone upon which a bird is really carried when supported by the action of its wings in the air. In the bat, on the other hand, the shoulder joint is supported by only two bones, and therefore the bearing up of the body in flight is thrown as much, if not more, upon the muscular attachment of the blade-bone to the ribs as upon the sternum. The bat is thus supported in its flight in the same manner as other mammalia are supported in their motions, in which the feet are the points from which the motion is taken, and the origin of it is from solid substances; and the remarkable part of this structure in the bat is such a modification as enables it to originate motion by striking its extremities against the air. To produce this modification, there must be powerful muscles to depress the wings in taking the stroke; and in order that those muscles may act with proper effect, they must have a place of origin proportionally firm to that of the joints of the bones to which they are attached. For this purpose the sternum is provided with an elevated keel along the mesial part, and to this keel the principal muscles which depress the wings are attached.

The bones of the fore-arm, and more especially those of the metacarpus and the phalanges of the fingers, or as we may call them, the four external toes, in each of the fore extremities, are very long and slender in proportion to their length, so that this part of the skeleton is slender and light to its extremity; and these terminal bones spread very wide at their extreme points. The thumb or inner toe on these extremities is comparatively short, and it is furnished with a strong and very crooked claw which assists the animal in suspending itself from the rugged surfaces to which it clings, and also in its slow and crawling motion upon the ground. From the nature of the shoulder joint in wanting the third means of support; from the length and slenderness of the bones, and the distance to which they are spread from each other at their extremities, and from the immediate organ of flight being membrane supported by bone and not feathers, this wing is much less efficient in proportion to its size than the feathered wing of a bird, and it is incapable of that

peculiar twisting motion in the elbow joint which makes the bird's wing act to the greatest possible advantage against the air. The bones in the extremity of this organ of flight are indeed the very reverse of those in the bird's wing, for while the terminal bones of that wing are soldered together, so that it strikes the air in one mass, those of the bat's are spread out, and the stroke upon the air is divided into as many parts as there are finger bones supporting it.

The production of the wing membrane too, which is often continued, with more or less interruption in the middle part, to the hind legs, and sometimes forward to the ears, and also backward so as to include the tail, does not allow the same freedom on the first or shoulder joint of the wing as birds possess; and from these circumstances the style of their flight bears more resemblance to the flutter of the larger insects than to the clean and effective strokes by means of which an air bird dashes along. Some details of the different parts of their structure will be found on referring to the article *BAT* in this work; but in order that we may better see the contrast between them and the other mammalia, as well as between flying mammalia and birds, there are one or two particulars to which it is necessary to advert. The flexible spine, the weight of the hind legs and the tail, and also some physiological considerations, render it necessary that the wings of the bats should in part support the posterior extremities by absolute connexion with the moving part of the wing, and not through the medium of its insertion; and there is this reciprocal advantage in the membranes which extend from the wing, that they steady it, and prevent such an action of the large blade-bones against the ribs as would otherwise take place in consequence of the weight of the body being less completely borne upon the sternum than it is in birds. Altogether, the wings of bats are to be considered as peculiar modifications of the anterior extremities of mammalia for a specific purpose, and not as bearing any structural analogy to those of birds.

In the posterior extremities, and these partake but little in the motion of the wings, though they yield to that motion, there is perhaps a still greater deviation from the usual form of the mammalia. These legs have, in the hip joint or articulations of the femur, a sort of half revolution outwards and inwards upon an axis, so that when the legs are bent, the toes and the legs are directed towards the belly, while the thigh is directed backwards. This arises in part from the backward situation of the cavities into which the heads of the femurs are inserted. This moving of the knee joint backward, while the foot and leg are brought obliquely forward, enables the first of these joints to tighten the posterior part of the membrane into a parachute, while the contrary flexure of the foot forms a cavity at each side, and so makes it take a better hold on the air. This species of resistance will be better understood by those unacquainted with the mechanical properties of the air, by noticing how much more speedily a little cap made of paper falls to the ground when the projecting side of it is turned downwards, than when the hollow is in that direction. This converting of the hinder part of the membrane into a parachute, which is supported by the resistance of the air under it, owing to its escape being prevented by the lateral bending downward, compensates in some sort for the imperfections of those parts of the membrane which are moved by

the arms, and perform the active part of the flying. The membranous wings do not, like the feathered wings of birds, admit the air to pass through them when they are raised, and in consequence of this, excepting in so far as the rising wing is contracted in size by the flexure of the joints, as compared with the descending wing, which takes effect with the joints extended, there is not much in the structure of the bat's wing to make the one side of it offer less resistance to the air than the other does; and this is the reason of the great rapidity with which the wings are moved both ways, the parachute portion holding on until the moving part has gained its elevation, and is ready to descend again.

The whole structure of the bats, and more particularly of those which fly high and with considerable rapidity, is so formed as to give them a very great horizontal surface in proportion to their weight and length. The wings and continued membranes are not only very large, but the body is short and broad, which both increases the horizontal surface, and affords more room for the pectoral muscles. The posterior part of the body is made slender, and all the parts with which the anterior of the body can be loaded, consistently with the functions of mammalia, are situated there; for instance, the mammae of the females are pectoral, and when they carry their young on their flights, these cling to the breast.

The wings of bats are not capable of bearing nearly the same exposure to the atmosphere and the sun as the wings of birds. The membranes possess a good deal of sensibility, and their motion would be rendered much more stiff and difficult if they were to become dry. Hence bats, at their regular hours of appearance, are never seen on the wing when the wind blows strongly; nor, notwithstanding their love of shade and humid air, especially in hot countries, are they ever seen during heavy rain; it is probable indeed that the violent rains which prevail in those tropical countries would beat them to the ground, just as a tropical hurricane would deprive them of all command of the air, and drive them before it like chaff. A high temperature appears, however, to be essential to the proper working of their very curious structure, for they hybernate not merely in the cold latitudes, but in those which are moderately temperate. They are creatures of gloomy caves and stilly twilights; at which times they beat the air with great industry, and most of them are very ravenous, even the ones which feed upon vegetable substances.

The peculiar flexure of the legs to which we have alluded, which turns the toes of the hind feet inward, is of great advantage to them in their manner of resting, which is usually that of suspending themselves upon the sides and the inequalities of the roofs of those caves, ruined temples, deserted houses, and other places where they take up their abode. The crooked claws upon the thumbs of the wings take hold with their points so situated, as that the axis of each is directed nearly toward the centre of gravity of the body, and thus the weight draws them, or tends to draw them inwards as well as downwards; the crooked claws again on the hind feet are by the position which they take when bent, so placed, as that they are drawn, or tend to be drawn, outward and downward; and as they have the line of their action also directed nearly from the centre of gravity of the body, the weight of the body tends to make each hind claw pull so as to tighten the fore claw on the

opposite side, and thus the two holds give firmness to each other. The hind feet have five crooked claws on each, and as they have in addition bent legs to press them to their points of adhesion by the weight of the body, they take a greater hold than the thumb claws, proportional to the greater weight which they have to sustain.

In consequence of this disposition of the claws when the animal is in a state of repose, very small irregularities of surface will enable a large bat to maintain its place with great firmness. Its position too is a position of perfect repose, and not one maintained by muscular exertion, for the whole is done by the elasticity of the tendons and ligaments. There is yet another peculiarity in this position, especially that of the hind legs, when the animal wishes to get into motion, the unbending of the hind legs throws the axis of the body upward, and opens the parachute, so that the air is under it, and the wings are ready for acting in flight, the moment that the hooks of the thumbs quit their hold. Getting to the wing from the ground is a much more serious matter, and we believe it may be said that, generally speaking, bats crawl up some surface which is perpendicular, or nearly so, when they take the wing. They are so seldom seen on the ground, however, that it is impossible to speak with perfect confidence about their movements under all the variety of circumstances to which they may be exposed, except by analogy from their structure.

On the ground, the action of the bat is peculiarly awkward, more so than that of any other mammalia. They cannot walk on all fours in the usual style, and as little can they, from the singular way in which the hind legs are articulated, and the weight of the fore part of the body, raise themselves into an erect position and walk upon these legs. The shoulder-joints are articulated for motion across the axis of the body, and therefore, independently of the awkward form of the terminal portion of these extremities, the humerus cannot be advanced so as to take any thing that can be called a step: they are therefore reduced to a very odd sort of motion; they advance one side of the body a little, which advances the bend of the wing or elbow joint on that side, and having done so, they lay hold in advance with the claw of the thumb. This being done, they, by the unbending of the hind leg, swing the body round upon this claw as a pivot, by which operation, the turn of the wing on the other side is brought in advance, and grappled by means of the thumb claw in the same way as the former. Repeating this operation with each side alternately, they contrive to wriggle along by a course something like that of a ship working board and board upon a wind, and thus the resulting course is in a straight line, though the actual motion is performed alternately right and left. A motion which is so laborious in the performance, and in which so little progress is made, can be of comparatively small use to the animals, as it can neither serve them in following their prey, or in escaping from an enemy. They therefore resort to it only in cases of necessity, and if they have to practise it for any length of time, they are completely exhausted.

Bats are the only mammalia which can actually fly—that is, which can renew their motion by gaining a fresh impetus from the stroke of their flying membranes against the air; for all other animals which have produced membranes which they can extend by

stretching out their legs laterally, use those membranes only to prolong a spring which is originally taken from some solid fulcrum of resistance. A contrivance of this kind would be of little or no use to a ground animal, because the less resistance the air offers to such an animal, the more rapidly it can proceed, and also with the less effort of muscular strength, consequently, those parachute membranes as we may term them, are found only among climbing animals, and among that description of them which do not make their progress by grasping, but by running along the branches, and holding on with the claws. Some of them, however, have a great deal of freedom of motion; and the common squirrel, the membranes of which are very little produced, can make its way very rapidly through the upper branches of a clump of trees; and even when it is alarmed, it very rarely misses its footing or its hold, and falls to the ground. The proper place to mention such animals will be, however, that where we treat of climbing organs, and the auxiliary organisations, by means of which climbing animals contrive to pass from branch to branch, or from tree to tree, when the distance is too great for being reached by their limbs, or cleared at an ordinary leap.

Organs of Swimming.—As the bodies of almost all mammalia, when the lungs are inflated with air, are of nearly the same specific gravity as water, they may be said to be all capable of floating in that element; and as their so floating does not deprive them of their powers of locomotion, they in general can row themselves along by the action of their feet. This is a sort of swimming; but still with exceedingly few exceptions, if indeed there are any, mammalia of this description have the feet as well if not better adapted for some kind of motion upon land than for this description of swimming. When the water is to a considerable extent the pasture or the element of these mammalia, as in the case of the beaver and the otter, the hind feet have the toes webbed; and there are some instances, such as that of the ornithorynchus, where the webs of all the feet are very much produced; but animals having this structure, live habitually in the water, unless when they come up to breathe, or when one pool dries up, and they have to seek their way to another. The motions of none of these, whether performed on the surface of the water or under it, is the characteristic swimming which distinguishes the proper vertebrated animals of the waters, the fishes, from the other three classes. The seals and narwhals have much more of the swimming habit; but still they are capable of some motion on solid surfaces, for they can creep and they can climb, they therefore retain in part that character of the extremities which is perfect in land mammalia; and in order rightly to understand the typical organisation of mammalia for swimming, so as to be able properly to compare it with the organisation of the same general structure for the other kinds of motion, we must turn to the cetacea.

In the article CETACEA there will be found an enumeration, of the principal species, and some account of their structure and habits, so that all which remains to be done in this place is, to take the most typical one in illustration of the whole, and there is none so well adapted for this purpose as the common Greenland whale (*Balæna mysticetus*), which is unquestionably the best and the most constant swimmer of the race. There is sufficient reason why this should

be the case, in the mode of feeding of this species of whale as compared with that of other whales, and in this respect there is a correspondence between the sea mammalia and those of the land. In both situations, those species which take their food in the smallest portions, or which have it of the least nutritive quality, which comes exactly to the same in effect, are most constantly feeding, and by necessary consequence most habitually in motion; though animals which subsist upon larger and more nourishing prey, and which require more violent efforts in the capture of it, can move with greater velocity for a short time. In respect of the proportion which the individual morsels of its food bear to its own size, the Greenland whale may be said to be peculiar among the mammalia. It is among the largest, if not the very largest of the class; and yet the animals on which it feeds are smaller than those which a common cat finds for itself in a state of nature. This food also floats at no very great depth, and consequently the whale is a surface feeder, and though its food is animal, and its digestive system in accordance with this, its ranging the ocean for its subsistence, in so far as the mere moving is concerned, bears no inconsiderable resemblance to that of a ruminant animal in browsing the herbage of the ground.

It is necessary to take this habit of the whale along with us, in order that we may rightly appreciate the particular form of its organs of swimming, and also that general shape of the body which gives those organs the greatest possible efficiency in the element in which the animal lives.

In as far as the head, the trunk, the tail, and the anterior extremities are concerned, the parts of the whale are numerically the same, and placed in the same order as in other mammalia; but the posterior extremities are altogether wanting, and though the internal structure of the mammalia requires that there should be a pelvis of some kind or other for supporting the abdominal viscera, yet this pelvis is very rudimental in the whale. [It is to be understood that when in this part of the article we use the word whale without any qualifying epithet, the Greenland whale is always meant.] The rudimental pelvis consists of three little bones, the middle one of which answers to the two bones of the pelvis in ordinary mammalia; and the others, which represent the haunch and hip bones, are only a single elongated and very slender bone upon each side. These bones serve merely to give a little stiffness to the flesh at the place where they are situated; and thus prevent the violent action of the grand swimming organ from jerking and disturbing the viscera, more especially the lungs, so much as it otherwise would do. They are not in any way articulated upon the spinal column, neither is there any appendage with a bone in it articulated upon any of them, either external or internal of the animal. By this means, while they prevent injury in the way which we have stated, they allow perfect freedom of motion to the spine. That spine is the grand basis of locomotion in the whale, and all the parts of the animal are adapted for giving it the very maximum of effect. As is the case in all the mammalia, its principal flexure is in the mesial plane, in bending upward or bending downward; but after the more essentially vital parts of the animal are past, the posterior part of it has both lateral and twisting motions. The vertebræ of the neck are exceedingly short for so large an animal, but they are always the

same in number as in land mammalia, and they have remarkably little motion. With the exception of the anterior extremities, afterwards to be noticed, and the broad and bilobed expansion of the tail, there is no projecting member upon any part of the body of this animal, which can either accelerate or retard its motion through the water. In this respect it possesses an advantage over those whales which have a fin on the back, because this fin prevents the body from turning round with the same ease and rapidity.

The body of the whale is thus so formed as to be perfectly obedient to the operation of the few swimming organs which it possesses; and it is besides so formed as that these can act to the greatest advantage, while it offers the least resistance to the water which could be offered by an animal of equal volume. Its skin is perfectly smooth, and it is kept always soft and flexible by the great quantity of soft fat which lies under it.

The anterior extremities, or "fins," or "swimming paws," as they are sometimes termed, are not organs of progressive motion, neither are they organs of ascent and descent, like the pectoral and abdominal fins of fishes. In moving, their chief use is to turn the body round on its axis, or to assist in enabling it to perform loops or doubles in the line of its movement. We introduce a cut of the skeleton of a

swimming paw of the whale. The bones of this member are the same in number and arrangement as those of the land mammalia—a blade bone, a shoulder bone, two bones in the fore arm, carpal and metacarpal bones, and four fingers. They are, however, much flattened in their planes, and their articulations have little motion upon each other, though their cartilaginous unions give them much pliability, and they have very powerful motion at the shoulder joint. These swimming paws, from the office they perform, can obviously act most effectively by being situated near the centre of gravity of the whole mass; but as the neck is very short, they are near the anterior portion of the spine; and thus, as the whole of the spine, from their position backwards, is efficient as an organ of motion, this organ would have no fulcrum at all competent to give origin to its powerful action, if there were no more in advance of the insertion of the paws than the short neck and a head of the ordinary size. To make up for this, the bones of the jaws are produced to a much greater extent in proportion than they are in any of the mammalia, with the exception of the cachalots or spermuceti whales. The organs of the senses are situated far backwards in this great production of the head; but as it does not appear that smell or even taste is exercised in the feeding, the eyes, which are the most efficient

organs, are more advantageous in their backward and lateral situation. In consequence of the shortness of the neck, and the great production of the bones in advance of the skull, the fore part of the whale is a large mass which has little or no flexure in any direction; and thus it gives a firmer point of insertion to the movable portion of the spine than we meet with in any land animal, not excepting even the shoulder joint of the strongest winged hawk or the most powerful eagle.

This flexible portion of the entire length is a cone, tapering finely off, and gradually less heavy in its bones, and more free in its joints, as it approaches the extremity; and at that extremity there is the expansion of the tail, of which the following is a sketch.

It will be seen from this figure that the tail consists of two lobes, the posterior edges of which are curved with a double flexure. This instrument does not consist of a series of bones, like the terminations of common mammalia, neither is it extended upon rays, like the tail fin in fishes. It is in fact not a fin, though it is usually so called; but it answers the purpose of one, and answers it with wonderful effect. Its external covering is scarcely different from that of the rest of the body; but internally it is composed of tendons, exceedingly numerous, remarkable for their strength, and capable of very varied as well as most powerful motion. These tendons consist of three layers, two of which, external on each surface, follow the direction of the lobes, and the internal one crosses them obliquely. These tendons are connected with a great number of muscles inserted on the processes of the spine, and they pass through a great number of pulleys of ligament, so that, though the general motion of the tail as a whole is striking upward or downward against the water, the number of oblique motions and changes of flexure of the lobes is countless. As with the exception of the muscles connected with the swimming paws, which are comparatively few and weak, the whole motive energy is concentrated upon this organ, it is equally ready and powerful; and perhaps, considering it as capable of giving a blow, it is the most efficient organ in the whole animal kingdom. The texture of the portion of it which takes effect is also such that it can hardly be injured. It is so tough that it cannot be torn, and so free from feeling that a stroke of it against a hard substance gives no pain to the animal. If it strikes a boat across the middle with the edge, the boat is cut asunder as clean and as speedily as if by one stroke of a giant axe; whereas if it strikes with the flat of the lobes, the boat is driven to the depth of many fathoms with the swiftness of an arrow. Those who attack the whale in its strongholds among the polar ice are aware of the fatal effects of those blows, and therefore they are studious to avoid them.

In swimming, we need not add that this instrument must be most efficient. It is placed at that part of the animal where a paddle or oar has the greatest effect; it has, as we have said, a steady point of insertion, and the vertebral column which supports it tapers at that rate which combines the maximum of strength and elasticity; and therefore, without the assistance of fin or scale, or the deriving any assistance from contrary flexures of the body, it dashes the animal onward at an exceedingly rapid rate.

The absolute rate of the whale's motion is of course not known, and cannot be known, as a mathematical quantity deduced from actual experiment, in which both time and distance are known; but some theoretical estimates which have been made, founded on the form of its body, and the force with which its swimming lobes strike the water, lead to the conclusion that the rate of its progress exceeds twenty-two miles in the hour; and this is not unlikely, because many birds which have to bear up their weight in the air are capable of moving at a far more rapid rate than this, and continuing their motion for many hundreds of miles. On this subject, however, it is impossible to speak with precision, but we may well suppose that in animals so finely constructed for progressive motion, and nearly of the same weight as the medium in which they move, the rate of motion may be even more rapid than this. Such powers give these animals full command of the most extensive oceans; and as, when the polar seas are frozen in the northern hemisphere, we do not find the whale migrating to the temperate seas of the same, as is the case with those birds which are frozen out of their polar quarters, it may be possible that these whales range from the one polar sea to the other. It is true that they are not found in the middle latitudes, apparently resident for a season, as the spermaceti whales are; but there is not a great deal of stress to be laid upon this, inasmuch as the spermaceti whales, being furnished with teeth and having wide throats, can find food in any sea where fish abound (and surface ones abound most in middle latitudes); whereas the Greenland whale, dependent on the small animals which it can catch in its whalebone net, can subsist only where such animals abound, and it should seem that those fitted for the food of the whale are most abundant in the high latitudes and during the summer season.

Besides their effect in turning round the body on its longitudinal axis, the swimming paws of the whale perform other functions. Their proper motion is a cross or clapping motion, so that one whale can embrace another by means of them; and the mother whale can carry her young in her arms, until it acquires sufficient size and strength for swimming by her side.

There is another use to which the animal is enabled to turn these swimming paws. When extended they form a line of considerable length at right angles to the axis of the body, something in the same manner as the trunnions form a line at right angles to the line of metal in a gun; and the whale can move the axis of its body in the vertical plane upon them, much in the same manner as the gun is moved upon its trunnions. By this means, the whale can descend to a depth and rise to the surface to breathe in much less time, and with much less range in horizontal distance, than if its motion were regulated by the tail only. The length of time that the whale can remain under the water before it rises to breathe is under-

stood to be about twenty minutes; but it often plunges to such depths as that more than this time would elapse before it could get up again, if it had to proceed upon so long a slope as the action of the tail alone would require. But, by the paws acting as a sort of axle to it, it can turn the axis of the body upwards or downwards with great rapidity; and it can both descend and ascend in nearly a perpendicular direction. It sometimes descends with so much rapidity as seriously to injure itself, by striking the bottom at a great depth; and Scoresby mentions an instance of a harpooned whale descending perpendicularly with so much rapidity that it fractured its skull against the bottom in a depth of 800 fathoms. At such a depth the pressure on the body of the animal is far greater

The Plunging Whale.

than what it is nearer the surface; but, as the difference of pressure between the two extremities is only in proportion to the different depths of water above them, the resistance of its descent is not proportionally greater in deep water than it is nearer the surface. Beyond a certain depth, however, it should seem that the pressure of the water squeezes even the substantial carcass of a whale together, so as to expel the air from the lungs, and otherwise greatly increase its specific gravity; for when a wounded whale plunges beyond a certain depth, it sinks in the abyss like a stone, and never again returns to the surface.

The cetaceous mammalia which frequent the fresh waters, or are found only littoral or near the shores, and which from this habit have no occasion to plunge to such depths as the pelagic ones which range the wide oceans, have not the same enlargement of the bones of the face, and it is obvious that, from the comparatively small depth of water in their haunts, they have not the same occasion for it.

The two kinds of organs of motion in the mammalia, of which we have given a slight notice, in the structure and action of what may be considered as the most perfect or typical form of each, may be con-

sidered as one general class, namely, motion in an animal taking its origin from a fluid as a fulcrum; and this general class readily divides itself, according to the nature of the fluid which serves as the fulcrum, into two sub-classes or orders. The first of these, and that which we may presume to require the greatest effort from animals having the general structure of the mammalia, is motion originating in atmospheric air, which we have exemplified in the bat family, the only mammalia which in reality are capable of performing it. The second is that where water, the other abundant and generally distributed fluid connected with the earth, affords the fulcrum. This, from its greater specific gravity, more nearly approaches to being the natural element of the mammalia than the other does; and therefore, as we have said, there is scarcely any of the mammalia but which can originate motion from the resistance of water, so as to keep its body buoyant in that fluid, at least for some time. If, however, the animal has not, in the structure of its organs of motion, some adaptation to the water, progressive motion through the water is far more fatiguing to it than progressive motion through the air with the earth as a fulcrum from which to start each successive movement. There are two causes explanatory of this: in the first place the motion of the animal has far more resistance to overcome in the water than it has in the air; and in the second place the fluidity of the water makes it give way to the stroke of the foot, in such a manner as that great part of the effort is wasted in the recoil, and it is only the surplus after this waste which can go to the progressive motion in the animal. We have a very familiar but very forcible illustration of this, in the different rate of current which a man can stem with ease in the air from what he can stem in the water. The wind or atmospheric current may be blowing at the rate of twenty, fifty, or even more miles in the hour, and yet a man who leans forward upon it, and gives himself the advantage of the bent leg in front and the straightened leg in the rear, can not only keep his ground but make tolerably rapid progress against it. If, however, a current of the water sets even nearly as fast as a man can walk on land against a pretty stiff breeze, the current of the water bears him along with it in spite of his utmost efforts. There is no doubt that, on the land, the man has the advantage of the solid fulcrum to spring from, and also of the comparatively small resistance of the gaseous fluid against which to make his advance; while, in the water, he has to make his way against the resistance of the denser fluid, and at the same time the current bears his fulcrum away from him with a rapidity proportional to its velocity.

It is not difficult to give a rude estimate of the different resistances with which the man has to contend in these cases. In round numbers, the weight or power of resistance in water is about 800 times as much as that in atmospheric air; and, as it is generally understood that the impetus or effect of bodies in motion is directly as their quantities of matter, and inversely as the squares of their velocities, if a man's body presented the same surface to the wind as to the water, the mere resistance of the water alone without any motion would be equivalent to that of a current of air having a velocity of about twenty-eight miles in the hour. But as a man does not swim through the water as he walks through the air, it is not easy to state the proportion of the resistances in any thing like correct terms. It is also to be taken

into the account that the arms tell much more in swimming than they do in walking. In walking, from the comparatively trifling resistance in the air, the arms can be regarded as very little else than balancers; whereas in swimming they are real organs of progressive motion; and as in advancing them to the front they can be feathered, as a rower feathers his oar, so as to offer much less surface to the water than they do when striking against it to give the forward impulse, skilful management may convert them into very efficient swimming instruments. There are several circumstances connected with the pressure of water, when the body pressed on is completely immersed and under the surface, which are not unworthy of attention. Among these we may mention how much more easily the body of an animal is lacerated, or any substance cut by a sharp instrument. The substance stands up to the instrument, both on account of the compactness of its parts, from the pressure (if it be a compressible body), and also from the water's keeping it against the cutting substance, being so much greater than that of atmospheric air. Owing to these effects of water, many substances can be cut when submerged by means which have no influence upon them, when the attempt is made in the common air. As an instance of this, it is said that, under water, glass may be cut into any shape by means of a pair of common scissors; whereas, in the atmosphere, it cannot be cut by the same instruments without a very great effort, and that effort splinters it to pieces instead of cutting it in any definite direction.

So far as we are aware, atmospheric air and water are the only fluids in which any of the mammalia can live, if they are fairly submerged, or included in the volume of them. The common mammalia which require very frequent respiration of the free air cannot remain for any length of time under water; and therefore, in their progressive motions through that liquid, which are not swimming in the proper sense of the term, but merely a species of walking, except in the case of man, who brings into play in this situation his arms and hands which are not available for locomotion in ordinary cases, they require to keep the nostrils, or entrances to the breathing apparatus, above the surface, otherwise they soon get suffocated by the entrance of water into the lungs. The vulgar notion is that the water thus taken into the cavity of the land mammalia when they are submerged is taken into the stomach, but this is a mistake, for nothing can be taken into the stomach but by an effort of swallowing; and even though water were taken into that viscus, in as great quantity as the pressure of a moderate depth could force it, it would do no great harm, if it did any harm at all. But when the water gets into the cells of the lungs, the case is very different. It not only prevents the contact of atmospheric air with the capillary vessels for the time that the animal is in the water, but it lodges in the cells; and as the lungs are capable of expelling only air, together with the quantity of water which it may hold in a state of vapour, and this differs in different mammalia according to their temperature, there are no natural means of expelling the water or restoring the animal, without it can be so inverted as to make the water run out, and that the lungs can be so excited by some stimulus as to promote the expulsion.

The old opinion was, that in the human subject, and by inference in all the other land mammalia, if the *foramen ovale* or internal passage between the syste-

matic side of the heart and the pulmonary, which exists in the foetal state, could be kept open, life would be preserved for a long time under water. This, however, is not the case, for it is the want of atmospheric stimulus to the blood and not the want of passage which causes strangulation, in drowning, and in every other case in which atmospheric air is not freely admitted into the lungs; and this particular passage in the heart is of use only as long as the young animal receives its nourishment from the arterial blood of the mother, which blood has already undergone the requisite operation of the air in respiration, and though it were kept open in after-life it could be of no service whatever.

Mammalia, whose habit it is to remain for a considerable time under water, do not so remain in consequence of any passage in the heart resembling the *foramen ovale*. They so remain, because the volume of their lungs is proportionally larger than that in animals which must breathe more frequently and therefore cannot remain so long under water; and besides this, such animals are generally provided with some sort of valves closing by pressure from without, by means of which water is excluded from the lungs, and the more completely excluded in proportion as its pressure is the greater. We find a provision of this kind in the otter and the seal, and in the cetacea it increases in proportion to the length of time which the animals can remain under water. In the fresh water cetacea it is less perfect than in the marine ones which inhabit near the shores; and in them again it is less perfect than in those which range wide oceans, and are capable of descending to great depths, as is the case with the whale. The blow-holes are the proper breathing apertures of such animals, and their mechanism is perfect in proportion as the animals are capable of plunging. It must be borne in mind, that though these animals throw up jets of water when they blow, they do not do this always when they breathe; and that when they do it, the water has never by any chance come from the lungs, any more than substances which are sometimes returned by the nostrils of land animals come from their lungs. The water thus discharged is the current which sets toward the gullet of the animal in its feeding, and as both the gullet and the entrance of the trachea are shut against it, it is carried upward to certain cavities in the bones of the head, to which the under passage is by valves opening inward of the cavity, and the upper passage by valves opening outward. When these cavities are full of water the expired breath from the lungs blows it out with considerable force, which is the cause of the jets which are sent up from the blow-holes. There are, however, many circumstances in the adaptation of aquatic mammalia to the element in which they spend the greater part of their time, that it would be impossible to notice in a sketch so limited as this; and so we must proceed to our notice of the organs of motion as fitted for the land, and the several adaptations which are connected with them.

As is the case with mammalia which originate the individual portions of their motion from a fluid fulcrum, so with those which originate these from a solid fulcrum, there are two sub-classes or orders; namely, climbers or those which ascend or descend upon trees, or other substances standing up from the surface of the earth, and walkers, or those which have the line of their motion parallel to the earth's surface,

whether that surface is level, or an ascent, or is descending. In the case of ascent or descent, there is of course a degree of inclination, beyond which no walking animal can execute its motion, though there are great differences in this respect arising from the structure of the organs of locomotion. Thus, for instance, if the fore legs of the animal are short in proportion to the hind ones, as in the hare for instance, the long hind legs project the body very readily and conveniently up hill in running; whereas, if an animal so formed attempts to proceed rapidly down hill, it is in continual danger of tumbling heels over head. Hence, coursed hares always endeavour to take the hill of the dogs, if there is one accessible to them; and if there is a sufficient length of hill they are safe, if not too much exhausted before; but if they are compelled to run down hill, they very speedily become the prey of their pursuers.

These two sub-classes, or orders of motion originating from solid fulcra, admit of far more diversity in the mode of performance, and require a much greater variety of organs, than motions in which air or water is the fulcrum. The reason of this is very obvious. Air and water are very uniform in their consistency. There is very little difference in the density of water at different depths, because water cannot be much compressed even by very heavy pressure. The movement of an animal through water, therefore, differs scarcely any thing in species, whether the depth be greater or less, and therefore the very same organisation serves equally for motion through it, whether the animal is near the surface or farther down. Atmospheric air differs from water in being more compressible, and consequently it varies more in density at different elevations above the mean level of the earth's surface. But still there is very little difference to a flying animal arising from this; for the resistance of the air to the progressive motion of the animal diminishes at probably a greater, and certainly as great a rate as its density. Something depends on the velocity with which the animal flies against the air; and the theoretical view of the matter being that the resistance is directly as the density of the medium and the square of the velocity jointly, a comparison might be instituted. This theoretical view never can be made, however, to agree with experience, or rather experience does not agree with it; for though it is nearly correct for moderate rates, yet, when we come to great velocities against the same resisting medium, we do not find the actual resistance to increase nearly so fast as the square of the velocity. For the purposes of natural history it is not necessary to go into those niceties; and we may assume that a flying animal gets along with nearly equal exertion in proportion to the rate of its motion at whatever height it may happen to be in the atmosphere. Or if there is a deviation from this, the circumstances of the case would lead us to conclude that flight is more easy on a high course than on a low one, for we invariably find that even birds of heavy flight rise high in the sky when they are to perform long aerial journeys.

Thus in all the flying mammalia, and also in all the swimming ones, there is little diversity required in the organs of motion; and when we have described those organs in one species, either of the one or the other, we are in possession of the knowledge of them all, excepting in so far as they may be modified by a participation in other habits, in addition to the flying

or the swimming. There is another circumstance which further simplifies the structural study of both these descriptions of mammalia; their extremities are never any thing else than organs of motion, unless they happen also to be weapons of defence, as is the case with the tail of the whale. In no case, however, do they in any way assist the animal in the seizing of its food, they merely conduct it to the locality in which the food is to be found, and thus we can study their system of motion, as a simple system unmixed with any other.

When, however, we come to the land animals, or those which take their movements from solid fulcra, the case is very different, and this renders their motions and their organs of motion a far more intricate study. There are no doubt some of them which are incapable of making much, if any, use of their organs of motion, except in moving from place to place; but the number of these among walking animals is comparatively limited; and among climbing animals there are scarcely any. The climbing foot is, from the use to which it is applied, almost necessarily prehensile in some respect or other, either in grasping like a hand, or in holding on by means of claws. When it takes the hand form, however much it may differ from the human hand, which is a universal instrument and not a grasping one, it is of course equally fit for laying hold of the food, as for grasping the branch of a tree or whatever else is the means of support in climbing. An animal which climbs by grasping, always requires to have clavicles, in order to support the shoulder joints in those cross motions which the action of reaching from branch to branch requires; the same may be said of climbing animals which use membranes, or even simply their spread out legs, to protract their fall when they leap; and so also do animals which climb by grasping the bole of a tree, or other comparatively slender substance between the feet in climbing. But, with the exception of the winged mammalia, and they have a little of it, all mammalia which have a cross motion of the fore legs, have also a motion of them forwards and backwards. Hence every such animal can bring the fore foot to the mouth, and when an animal can do this, it always uses that foot more or less in the management of the food. We see remarkable instances of this in the ape and monkey tribes, some of the former of which are so expert in the use of the hands or fore paws in this way, that they not only gather their food with them, and clear it from refuse if necessary, but they make use of the finger in picking their teeth, if any substance adhering to these or sticking between them gives them uneasiness. The squirrels and other climbing animals which do not grasp, but retain their hold or their footing by the toes and claws, have also remarkable power over the anterior extremities; and they carry their food to the mouth with their paws, and use the paws in preventing it from falling, when it requires considerable action of the jaws to reduce it to the necessary form.

Even those animals which do not subsist upon fruits which they pull from trees, or upon insects and other things which they draw from the holes of trees, but which are predatory in their climbing, and catch living animals, very generally use the foot, either for grasping the prey by means of crooked claws, or by striking it against the branch, and holding it there, until they can seize it, and if necessary dress it with the mouth.

Indeed there is scarcely any of the climbing mammalia which does not combine in its anterior extremities at least some other action besides that of mere climbing; and in consequence of this we never can have a clear understanding of the extent to which animals of this kind possess the power of locomotion considered simply in itself.

Even in walking animals which do not climb, or gain any height which they cannot reach at a single bound from a place of rest for all the feet, the fore legs very often have compound action. Thus, for instance, the elephant appears to have as ungainly a foot, and as ill adapted for any thing in addition to mere motion, as one can well suppose; and yet the elephant contrives to turn this apparently clumsy and unmanageable foot into no bad substitute for a hand, to co-operate with its curious proboscis in performing rather nice operations. The very tame and playful elephant which the Duke of Devonshire had at Chiswick, and which was equally a favourite for its mild disposition and its mechanical dexterity, held a soda water bottle very neatly with its foot at such an angle as not to spill the water that it contained, until it had extracted the cork with what may be called the thumb and finger of its proboscis; and after it had done this, and then drank the water from the bottle, it could hold the empty bottle in the same manner till it replaced the cork.

Very many other vegetable and miscellaneous feeders use the foot in the obtaining their food. Sometimes to hold the one end of the food till they seize the other with the mouth, and either cut off what they require with the teeth, or pull it asunder with a jerk of the head. Most animals that feed on the leaves of trees, occasionally use the foot in striking down the branches; and not a few of those which have to find their subsistence under the snow, employ the foot in scraping off the snow, in order to reach what they eat. The solid hoofed animals, whose native localities appear to be those margins of the deserts where the pools and the streams get very shallow during the drought, have the habit of scraping a little pit with the foot, in order to obtain a sufficient depth of water for quenching their thirst. The pig makes great use of the foot in feeding, both in holding on till he tears it, and in keeping down the ground while he draws up roots, after he has nuzzled off the surface mould, so as to reach the blanched part, which is his favourite morsel. So strong and so natural is the habit now mentioned in this species of animal, that they do not forget it in a state of domestication, and where they have not occasion either to pull roots, or to hold on till their food is divided. The countryman's criticism upon Morland's three pigs feeding, is an illustration very much in point here. That talented but eccentric artist was particularly fond of painting pigs, and equally faithful in his delineations of their forms. The three pigs was looked upon as a *chef d'œuvre* in animal painting, and the countryman was brought to see it, as something of the merits of which he could judge, and which, from its supposed faithfulness to nature he could not fail to admire. He studied it for some time with much attention, and upon being asked what he thought of it, replied, "They are much the shape and colour of pigs certainly, but after all they are not pigs."—"What in the name of wonder induces you to think so?" asked his cicerone with some astonishment. "Why, who on earth ever saw

three pigs feeding without one on 'em having his foot in the trough?" replied the countryman, clearly showing, that how well soever Morland had studied the forms of pigs, this countryman had been far more attentive to their habits.

There are few, indeed, of the walking mammalia where we do not find some use of their fore feet in addition to the mere operation of walking; and there are not a few which use the fore-feet, and especially the hind ones, as weapons of defence, and sometimes of attack. This last circumstance, however, does not interfere so much with any other habit of the animal as those which we have formerly mentioned. The particular way in which the foot assists in feeding depends not a little upon the nature of the food; and we have therefore to study the feet of those animals both with regard to the kind of their food and the places where they obtain it; the last of which is a very extensive and varied inquiry, and demands a good deal of acquaintance with natural geography before it can be turned to proper account. This, however, is an advantage rather than otherwise, for we have a double profit and a treble pleasure when the study of one science induces, or even compels us, to study another. Each science is in itself both a pleasure and a profit, and then there is superadded the higher and more mental pleasure which we derive from tracing the connexion between them.

When we think of the localities for which climbing or walking animals of some description or other must be adapted, in order that no portion of nature's great pasture may lie waste, we must look at the world in every zone and in every latitude, ascertain the character of every surface, both with regard to its form, its fertility, and the plants which it produces, we must take careful note of the peculiarities of climate and of seasons which belong to each, and we must take into consideration the general vegetation, and the other animals. We must do all these things, because in every place which is left to the course of nature all the parts of nature harmonise: and if we can once possess ourselves of the principle of this harmony, it furnishes a ready and an easy key to a vast number of particulars. This is in fact the grand generalisation to which all our inquiries into natural history ought to tend; and the mammalia are far preferable to any other productions of nature for being our first and best guides in this delightful and all-instructive path. The mammalia of a country are its most permanent animated inhabitants; they summer and winter there, and do not quit, unless the physical circumstances of the country alter, or the animals themselves are driven into other places, or extirpated by man. We must, however, leave the general subject, and proceed to some particular illustrations.

Organs of Climbing.—Mammalia climb upon such varied substances and for purposes so different, that it is not easy to contrive any general description which will include the whole of them. Trees are, however, the chief resort of climbing mammalia, and the most characteristic ones are the quadrumana or four-handed animals; in all their divisions, including apes, baboons, and the different species of monkeys. Then there are some other animals which climb with less perfect hands, such as the lemurs, the lorises, the galago, the ai-ai, and a few others. Bears and some other animals climb by clasping with the legs, and partly also by the help of their claws; and there

are several others which use the claws chiefly in ascent, such for instance as the climbing cats, and some other tree animals, the greater part of which are inhabitants of India. The squirrel tribe have a compound mode of climbing; they ascend the thick trunks of trees by the help of the claws, by leaping, and by supporting themselves with their flying membranes, and their very much produced tails, which act as parachutes, as the peculiar character of their fur takes a considerable hold on the air. They thus leap among the small branches, more after the manner of birds than of common mammalia, though none of them can take a fresh impulse from the air itself. Among the flexible branches and twigs of a tree, a squirrel, however, derives an advantage in leaping, something similar to that which a stage tumbler derives from his elastic boards. The animal alights on the flexible branch or twig from a considerable distance, and with a good deal of impetus, so that the force with which it bends the branch is much greater than could be given by the pressure of its weight. This force is impulsive, and therefore its effect lasts only for a moment, and when it is over the twig recoils against the mere weight of the animal, and assists in giving it impetus for a fresh spring. The rapid march of the squirrel along the tops of the trees is therefore not nearly so fatiguing as might be imagined by those who do not reflect upon the assistance which it gets from the elasticity of the tree. In ascending or descending from near the extremity of one branch to near that of another, these animals, and indeed all animals which ascend or descend by these, derive similar advantages, though the mode in which they derive it is not exactly the same in the ascent and the descent. When the animal ascends and catches an elastic branch, whether it catch it with a grasping hand or by any other means, the recoil of the branch throws it upward, so that it can reach a higher one at the next spring than it could do if it started from a nonelastic support; and thus it proceeds until it gains the elevation at which it either finds its food, or gets beyond the reach of its enemies. In descending the recoil of the branch tends to throw the animal upward, and this enables it to descend upon the next branch with more velocity, and by this means leaves it with more command of its grasping organs. In fact, the elasticity of the branch adds very much in the way of a parachute in breaking the fall of the animal, so that an animal incapable of grasping while it descends, falls through the elastic twigs of a tree from a considerable height with much less injury than if it fell through a half, or even a third, of the same height without any elastic interruption. Every twig or yielding branch that it touches, takes off a considerable portion of the velocity which it has acquired during the previous fall; and it would not be difficult to suppose branches so tangled and so elastic, that a man might tumble through twenty thirty, or forty feet of them, and reach the ground without any material injury.

Among all this variety of mammalia which ascend and descend on trees, besides several others which climb rocks and other steep surfaces, solely by bounding in some cases, and partially by the claws in others, the true climbers are those which are capable of comparatively little motion upon the ground, and are very seldom found upon it, except when they have to make their comparatively slow and ungainly journeys from tree to tree, or from the trees to the water.

There is, however, a gradual change of character in the climbing organs, even in the quadrumana, until they ultimately terminate in what may be termed simple hooks rather than hands, having the fingers, or strictly speaking the toes, furnished with long sharp and bent claws, so that they climb either by bending the toes across a branch, or make their way longitudinally clinging by means of the claws and the spread of the toes. Animals which have this structure are all nocturnal, living in obscurity in the depths of the forests, and feeders upon insects, small birds, and very small mammalia, upon which they steal in the dark; and therefore we are but little acquainted with their habits in a state of nature, and capable of judging only very imperfectly of the manner in which they use their feet in climbing.

Perhaps the most typical of the climbing animals, which climb by means of hands, or more correctly grasping feet, for there is really no true hand in the whole range of animated nature except the hand of man, are the apes properly so called, namely the tailless ones, which have no appendage to the sacral extremity of the vertebral column, either as a balance in their motions, or as an additional grasping instrument.

Attempts have often been made to institute a parallel between those animals, more especially the chimpanzee and the human subject; and it has been supposed that this parallel extended even to the length of intellectual sagacity. This last, however, is completely without foundation, and even the mere animal motions differ in kind and not in degree. In the fore foot of the chimpanzee, and of all those apes which take their food with the paw, and prepare it if necessary by means of the two paws; the paw has a double function to perform, being equally a climbing instrument, and a prehensile one in the article of their food, and along with the mere prehension, it can break that food or otherwise prepare it, which may be considered as an inferior kind of working, though it is really a part, and a necessary part, of the act of prehension; in proof of which we find it exercised to a very considerable extent by some of the clutching and the climbing birds. In addition to these, its double functions, when the ape is in the tree, the fore leg has a third function to perform, in the exercise of which the great development of the paws, and their pliable structure, are disadvantageous to it. This is the act of walking, when the animal finds it necessary to be on the ground.

The three functions are perhaps more complete in the chimpanzee than in any other of the apes, and therefore its fore paws can be applied to a greater number of purposes. These purposes may, however, be, generally speaking, reduced to modifications of three—taking food, climbing, and doing mischief, that is tearing things to pieces. An animal of this kind may be taught to sit at table, to use a knife and fork, or to drink out of a glass, which latter operation is sketched in the figure on the following page.

In all these, however, and in every action which such an animal can be made to perform, there is not the slightest resemblance to the action of the human hands, any farther than that there is a mere grasping. That grasping is performed chiefly by the long fingers, to which the thumb acts merely as a point of resistance, and no way directs the general motion of the paw, whereas in the human subject, though the thumb contains a joint fewer than the fingers, its revolving

motion upon its centre, acts more efficiently in directing the fingers than if it had as many joints as they, because when their extremities meet with the thumb at its greatest extent, any of the fingers is bent to a right angle at the second joint from the extremity, or this degree of bending is parted among the different joints.

If the chimpanzee were to bring its fingers with their tips in contact with the thumb, they would be so much more bent than they are in the human hand, and the thumb is in itself so short, that scarcely any motion could be given to the point of contact between the thumb and fingers, by action of the parts distant from the metacarpal joints. When, therefore, the chimpanzee (and the case applies more to any other ape) holds a small object between the tips of its fingers and that of the thumb, all the motion which it can give to that object must be produced by the joints of the wrist, the elbow, and the shoulder. In human labour, especially in the nicer operations, much of the work is done, with all above the wrist, and not a little of it with the wrist itself, in a state of perfect repose, unless when the entire hand requires to be shifted from one place to another. Such a hand, therefore, can work a long time at the more nice and delicate operations which are confined to moving the joints of the hand itself, without in the least fatiguing the arm or any other part of the body. In like manner, if a little more range in space be required, and the wrist be in consequence put in requisition, all the motions may still be performed without in the least disturbing the elbow joint, or fatiguing any of the muscles which are inserted upon the humerus. So also, if a more extended range in working calls the elbow joint into play, that may be put in motion without in the least disturbing the shoulder, or disturbing the scapular and pectoral muscles; and if it becomes necessary to call the shoulder joint into requisition, that may be done while the body generally is in a state of perfect repose. This may be reversed: the shoulder may be moved, and so may the elbow, the wrist, and all the other joints to the last phalanges of the fingers, without in the least moving any of the joints which are more distant, or fatiguing the muscles which produce the motions of these joints.

In the human subject, therefore, when properly formed and in a state of health, there is a perfectly distinct command over every joint and part moved upon that

joint, so that whichever of them is required for any purpose is always ready for that purpose, leaving the rest in a state of repose, though they are all ready to act in concert, when the action required is so complicated as to require their joint action. This is the true character of a working hand, a hand destined to do something higher and more noble than the mere animal functions of climbing, seizing food, breaking it if necessary, and carrying it to the mouth, and occasional walking, to which the fore paw of the apes, even in what is regarded as the most perfect of their species, is necessarily confined. It is certain that the great majority of mankind do not educate this hand in the way that it ought to be educated, and perhaps there are none who do so properly, and yet there is an inexhaustible fund of ingenuity in it; and, excepting where it is limited by physical resistance, or by distance too great for its reach, it would be a bold assertion to state one thing which it might not be made capable of doing. We find that even the rudest people soon begin the education of the hand; and the weapons of the houseless savages of the Australian bush, and also their fishing hooks and basket work, would perfectly astonish those of our rustics who are confined to the mattock and the spade, and such other heavy instruments as require the exertion of the whole body rather than that of the hand.

When we speak of "educating" the hand, we speak of man as being endowed with mind and capable of general education, both as respects knowing and as respects doing. There is something beautifully poetical in the two simple words, in which in the *Systema Naturæ*, the illustrious Linnæus draws the discriminating character of man: "Knowing himself," says the Swedish naturalist, and he says no more; but in this single touch the picture is perfect, for, of all the varied living creatures which people the earth, this can be predicated of man alone.

If the other animals knew themselves, that is if they were acquainted, or could make themselves acquainted, with the structures of their own organs, the modes of action in those organs, and the principles upon which they act, they would be certain to improve themselves by education; but the fact of their never rising above the original instinct, in the individual or in successive generations, is a proof that they have no such power. The instruction which some of them are capable of receiving, by care on the part of man, is no evidence of the slightest approximation to self-educating on the part of themselves; and the best trained horse and dog, which are favourites with their masters, and to a certain extent treasures to them, remain just as ignorant of their own structure and their own capabilities as the wild ass in the desert, and the dingo in the Australian jungles.

Now, notwithstanding all the fancied similarity to man in the structure of their bodies, and the similarity in the internal parts is as great as in the external, if not greater, there is not half as much susceptibility of imposed education in any of them as there is in the dog or the horse, or even in the seal. By nature they are gregarious animals, living more or less in troops; and the gregarious instinct is just as constant to the animal as any other instinct. Such animals follow each other, both in change of place and in action; and when they are separated from their kind, brought into a domestic state, and familiarised to the sight of other animals or of man, they

follow these, are fond of their sight, impatient of loneliness, and, so far as their organisation permits, they follow them in action as well as in locality.

The food and feeding of the chimpanzee and the other more typical apes, both in the teeth and the digestive organs, resemble those of man much more closely than those of any other animals do; and therefore it is perfectly natural to suppose that, as in a state of nature they seize their food and bring it to their mouths by means of their grasping paws, they should follow man in the use of a fork, a spoon, or any other intermediate instrument. Nor is it the slightest evidence of intellect of any kind on their part that they should occasionally be found, even in a state of nature, making use of a stick to help them in their clumsy march, or to strike down a fruit which they cannot reach with the paw; for when they are on the ground they help themselves along by grasping the bushes; and, on the trees, branches and stems are the means of all their progressive motions.

In the search of their food, however, except merely reaching it by climbing, very little resource is required. It is true that they have to climb, and to look, and sometimes search with the fore paw among the branches, for those fruits which form their chief subsistence, but they require no stratagem, and no powers of pursuit, inasmuch as their food is fixed to the tree or lying still on the ground, so that if they can see it, and it is accessible, they have nothing more to do than to seize it with the paw, against which operation it cannot from its nature make the smallest resistance. Hence the reason why the ape tribe can never be trained to do anything useful, however they may appear to imitate man in those actions which accord with their structure and with their habits in a state of nature.

There is therefore no gradation from man through the apes to the other animals, except in the bodily structure, and there it is very slight. Every species of ape, under what subdivision soever it may be placed by naturalists, is peculiarly fitted by its organisation for a certain locality, and out of that locality it is out of its element, and cannot exist without artificial means, nor prosper as it does in its own locality by all the artificial attention that can be bestowed on it. Not only this, but every species which differs structurally from another, has a different locality; and though the latitudes and the climates of those localities may be very nearly or altogether similar, it is probable that the animals could not bear a mutual exchange of place. Viewing the matter therefore in the most candid and careful manner, it is impossible even to imagine that there is any approximation to man, regarding him in his whole nature as possessing an intellectual principle, on the part of the apes, any more than there is on the part of any of the other mammalia, let their structures be as different from the structure of man as they may; all that we can say is, that each animal is adapted to a certain locality and for a certain purpose in creation, and that, though these localities and these functions vary exceedingly, the adaptation in the case of each of them is as perfect as that of any of the others.

If the apes resemble man more in their organisation than some other animals do, it only proves that their modes of life resemble, more than any other animals do, the mode of life in man when in that state in which he has the least mental resource. Nor is it unworthy of remark, as illustrative of this, that

the blacks of the central parts of the eastern Archipelago, the grand home of the long-armed apes, live somewhat in the ape fashion. They dwell in the fastness of the central forests, usually in little hordes, and inhabit the trees—the hollows generally speaking, as places of shelter, but still their dwelling is the forest. They cannot climb by the grasp of the feet, as apes climb by the grasp of their hind feet; but they contrive to make a very efficient instrument for climbing of the great toe, with which they can hold on, until they get a reach upward with the hands, with much more force than we who lose the use of our toes in the luxury of shoes—and frequently gain corns as our reward—would be apt to suppose.

It appears, therefore, that though the ape can do nothing to elevate itself to the rank of man in a state of civilisation, man may remain in a state, higher than the ape certainly, but not very much higher. In this state, which of course is that of the minimum of mental development, man is more helpless than any of the animals, and in what locality of the world soever he is situated, he is more out of his element. The reason is obvious, the strength and energy of the human body must be limited as well as those of the bodies of other animals; and as all the organs of motion and action in man are fitted for many more purposes than the same structures of animals, it must follow that their adaptation to any one purpose must be inferior, and that when man attempts to play the ape in the wild forest, or any other part played by another animal, he must do it in a very inferior manner. This inferiority in any single exertion of the mere animal is, however, a very great advantage to man, for it constitutes that "necessity," which is proverbially said to be "the mother of invention;" and if we are to suppose that at any time human beings were cast on a lonely island, utterly uneducated, and without the experience of others to guide them, this necessity would be to them the beginning of mental development, though the future growth would depend upon circumstances, and would be more rapid in proportion to the necessity, unless that necessity were so great as to break down with despair, instead of stimulating with hope.

We must therefore regard the hand, or grasping fore paw of the ape, as especially an instrument fitted for enabling its possessor to reach, pull and eat the fruit on a tree, and we may naturally expect that all its organisation should be in accordance with this, for the feeding of an animal considered merely as an animal, is the main purpose to which all its external organisation is directed, and therefore the structure and the feeding are reciprocally keys to each other. If we know the nature of the organs of motion and the teeth, we can easily say when and upon what the animal feeds; and conversely, if we can say when and upon what it feeds, we can form a tolerably correct notion of what its structure must be, at least in what we may call the working parts of its body.

We have already seen that the fore paws of the ape are incapable of performing the proper functions of hands, and their chief adaptation being for climbing, they are equally ill-adapted for performing the office of walking feet. Perfect clavicles are necessary for the cross motion of the anterior extremities, and because the ape requires a greater stretch of those extremities than man does of his arms, the clavicle is rather firmer, and the articulation of the shoulder more loose. The oblique motion of the elbow joint

too by which the fore legs are made to cross each other and the paws brought together or to the mouth, give a lateral shape to those joints, and throw more strain upon the muscles than there is in animals which have those joints moveable only parallel to the mesial plane, or with very little lateral motion. The wrist joint is also loose, and the great length of the naked paw which comes to the ground, together with the motion of the thumb, so far as it has motion, bring opposed to that of the fingers, makes the planting, and especially the raising of the foot both clumsy and laborious. No animals with perfect clavicles are indeed good walkers in straight forward motion, for they have to assist the action of the fore legs by the flexures of the spine, which throw the centre of gravity of the body alternately to the right and left, and thus they may be said to have a double labour to perform, compared with that which straight forward walkers require in passing over the same extent of absolute distance; they have to carry the weight of the body forward, and also to carry it alternately right and left. Hence, in bears and several other animals which are not habitually climbers, but which, though they do climb, spend in general more of their time upon the ground, the clavicles are always more or less imperfect, part of them being composed of cartilage more or less flexible according to the habits of the species.

The hind legs and feet of the apes have more exclusively a climbing character than the fore ones. They are not used in seizing the food, or in performing any other operation than that of progressive motion, or of holding on upon the branches of trees. The thumbs on them are, generally speaking, articulated far in the rear of the fingers, and turned obliquely inwards, so that they rather grasp against the opposite side of the entire sole of the foot than against the other toes. Those hind feet from their structure take a firm hold upon a branch, and they also afford a broad base for mere support. That base is indeed too broad for walking, and the hind legs are articulated in a manner which, however firm the soles of the feet were upon the ground, would give the animal very little stability upon them. But they do not even stand firmly, for the tendency of the thumb acting in a cross direction to the other parts of the foot, is to throw the foot on its external edge, a position which is the most tottering of any in the march of an animal. We have a proof of this in human beings, in whose legs there is no very apparent malformation, but who appear merely to have acquired a bad habit of turning in the toes when they walk. In this way, the foot, instead of being planted firmly on the ball of the great toe and the heel, which are the grand points of support for firm and steady motion, while the outside of the foot is a support against lateral shake, is thrown upon the central portion of the outer edge of the sole for its main support, and the ball or the heel cannot come to bear without a lateral totter. What some of the human race thus acquire, chiefly from bad habit, the apes have by nature, and that to a far greater extent.

This, however, is not the only disadvantage to which these animals are subjected in walking, in consequence of the peculiar articulations of their posterior extremities. The pelvis is remarkably narrow, which brings the articulations of the femoral bones very near to each other; and as the distance between

the articulations of these bones is the base which supports the body or trunk of the animal, in the apes, this basal line is much too short for maintaining the body of the animals steady in an erect position. It may appear singular to those who have attended to the statics of dead matter, where there can be no stability but on a basal surface, that the base of an animal should be a line. It is to be recollected, however, that the stability of the animal is not the stability of rest, but a stability which must admit of motion; and this is quite incompatible with a basal surface. It must be remembered too that the line joining the articulations of the femoral or thigh bones, is the base of stability to the trunk, head, and upper extremities only, and this stability in the cross direction, or in the mesial plane of the body, is obtained by flexures of the spine, while the stability on the basal line already alluded to, as well as that in the cross direction to this line, are farther secured by the position of the arms; so that in the motions of the parts above, the animal has really the power of giving this line all the stability of a plane, at the same time that it retains the freedom of it as an axis of motion. We believe this stability in motion is necessarily peculiar to the living structure, and could not be imitated even in the slightest degree by all the complication of mechanical contrivances to which man could resort, and it is thus one of the most beautiful instances of the superiority of a power of motion in the moving thing itself, over a power of motion applied to it from without—one of the grand distinctions, in short, between an animal and a machine, and a striking proof of the great inferiority of the latter.

Even this inferior extent and stability of the basal line of the trunk is not the only imperfection which, as an upright animal, an ape sustains in consequence of the principal adaptation of the hind feet being for climbing. The possession of an *os calcis*, or heel bone, is perfectly incompatible with the action of a foot which is to grasp in the same manner as the foot of an ape does; and the absence of such a bone is incompatible with a steady upright position of two feet, as a means of support, and at the same time of motion. In the human subject, the sole of each foot presents a basal line, and consequently the two feet, in which the lines cannot be brought close together, form a basal plane, stable in itself in proportion to the lengths of the lines, and the distance which the feet are apart from each other in a lateral direction, provided they are not so far apart as to strain the muscles and destroy their free action. The method of walking with the greatest safety upon ice, or any other slippery surface, with the greatest security, is no bad illustration of this. That method is to keep the feet a considerable distance apart, to take short steps, and to hold the joints of the knees and hips, and indeed all the joints, the action of which tends to steady the body in walking, in such a state of relaxation, as that every muscle telling in those joints may be at perfect freedom to act as necessity may require.

The two firm basal lines which the human feet afford, admit of progressive motion by the alternate advance of each; because the flexures of the body and the motions of the arms can be so regulated as to keep the centre of gravity of the entire structure directly over the line which is the base for the time, and while this remains the case, the body must be

K

perfectly stable. It seems, however, that for general purposes a line is requisite, in order to ensure this stability. No doubt, as we see in figurantes and posture-masters, the body may be so educated as to be balanced on a single point; but then, during such balancing, it is good for nothing as respects any other kind of action, and would of course be of no use in the natural economy of any animal. The same kind of stability may also be obtained by pirouetting or whirling round on the one toe, in which the body is kept up by centrifugal force, just as a top is kept up in the motion of spinning; but this again occupies the whole of the powers and the attention, and could not be any portion of the natural movement of an animal, in whatever manner that animal were organised.

With the exception of man, none of the mammalia possesses a line of stability in the foot, whatever may be the form of that foot; for though there are many animals which walk on the tarsus, the ankle joint has no support backwards, unless there is a heel bone, which none of them possess. An ape, therefore, in common with the rest, has a yielding basal line, and not a stable one in each of the hind feet; and therefore, though many of the species can stand up, they are always tottering, incapable of much action in the erect posture, wriggling in their attempts to walk, and very speedily tired. The chimpanzee is perhaps the best walker among them, because its limbs are shorter in proportion, and thus they have not so much lever power in their flexures; but still it cannot proceed far without calling in the assistance of the fore legs.

But, besides the short base between the articulations of the thigh bones, and the very imperfect basal lines furnished by the feet, the climbing structure of the hind feet of apes gives them other disqualifications for walking. The joints of the thigh bones are loose, in order to allow a great deal of motion upon the foot which holds on, while the anterior part of the animal is engaged farther up among the branches. The knee joint also has a far more rolling motion than is consistent with steady walking, and therefore, the march of an ape, whether attempted on the hind legs only, or performed upon all fours, has not the firm tread, nor does it show any of the more elegant paces either of a biped or a quadruped. That very flexibility of its legs, and also their length, enable it to leap with great agility, and, generally speaking, with agility greater in proportion as its legs are less adapted for walking. This is common in all vertebrated animals which have long, ungainly, and folded hind legs, as we may see in the frog, whose leap is longer in proportion to the size of the animal than that of a stag or a greyhound; but nobody ever saw a frog walking. It is something the same with the apes, and it may be stated as a general truth, that the longer their legs are, they are the more agile leapers, and the less capable of walking. Hence we see that in proportion as the limbs of those animals are better organised for one particular species of action, they are worse fitted for every other.

This is a very important principle in the study of the animal economy. It not only shows us that the supply of resource in every animal is so nicely adapted to the animal's necessity for that resource, that there is neither waste nor want, but a perfect sufficiency joined to an equally perfect economy. It shows us farther, that in studying the structure and economy

of any animal, or of any well-arranged group of animals, we have only one general character to study, which, when fully understood, carries us readily and briefly through all the details. Were it not for this last circumstance a knowledge of natural history would be altogether beyond the ability of the most zealous and long-lived member of the human race, because the acquired knowledge would never afford a means of arriving at the knowledge sought; and we should have the old simile of the bundle of rods with the band broken, and the strength dependent upon unity gone.

The larger apes of the south-east of Asia are perhaps still better organised for climbing than the chimpanzee, and in proportion as they are better adapted for that they are less so for walking. They are more exclusively forest animals, and march among the branches with so much rapidity that it requires a tolerably swift animal to keep pace with them on the ground below. Their anterior extremities are exceedingly lengthened, and thus they can extend their grasp to long distances in proportion to their size and weight. The great extent to which their legs fold without any straining of the joints, and the circumstance of their fore paws reaching the ground when the spine is not very greatly depressed from the horizontal position, enables them to spring from all four at once; and thus, when pursued upon the ground by enemies, if they can get near a tree they can spring and seize a branch at a considerable elevation. They, and indeed almost all the apes of the eastern continent, can also rest their limbs by reposing in a sitting posture, and embracing the tree with one limb. They are enabled to do this for a greater length of time than almost any other animal could, in consequence of the pads of callous and elastic matter with which the posterior parts of the body are provided; and though their habits during sleep are not much known, it is probable that many of them repose in the trees in this position.

The baboons are perhaps not so exclusively tree animals as the apes, but are more on the ground, and more habitually upon all fours. They climb well, but they do not leap with so much agility as the long-limbed foresters; they are therefore exposed to more danger from ground enemies, and therefore nature has given them more surly dispositions, and more powerful weapons of defence, in their long and strong canine teeth. We may remark that, though the teeth of the apes bear a very considerable resemblance to those of man, and that the baboons, notwithstanding their large canines, have no carnivorous cheek-teeth, yet that the whole of the race, even down to those of comparatively small size, have very powerful action of the jaws and bite desperately, more severely even than carnivorous animals of the same size and weight, though their bite is a cutting and not a tearing one. This strength of the jaws, and power of bite, are closely connected with the climbing character of the animals; for many of the fruits upon which they subsist are enclosed in such hard external coverings, that great force is required in order to get at the part fit for nourishment.

The very numerous species and genera of quadrupeds of the eastern continent, known by the common but ill-defined name of monkeys, all climb nearly in the same manner as the apes, and being more slender in their bodies, and thus capable of inhabiting smaller twigs, they are more frequently seen. They are, generally speaking, better walkers than the others,

and they perform their climbings and other motions in the trees, by leaping and by grasping jointly. Their tails, which in some of the species are very long, assist in steadying their bodies, both when they leap and when they walk, which they do upon all fours, and though with a leaping and shambling motion, yet a good deal more steadily than the quadrumana that have no tails. That their superior powers of locomotion on the ground correspond with the peculiarity of their organisation, is proved both by the observation of them in a state of confinement, and by the fact of their assembling in troops, and marching considerable distances, in order to plunder in the plantations of the people in the countries which they inhabit thickly.

When we turn our attention to the quadrumana of the American continent, we find considerable differences in their organs of climbing, and these are accompanied by certain differences in the number of the teeth. The most remarkable difference in their climbing organs, which however is not common to the whole, is the addition of a fifth one, which is equally efficient with the other four, if indeed it is not more so. This is a prehensile tail, or a tail capable of laying hold by curling once or oftener round the branch or other substance by which the animal wishes to support itself; and if we except the kangaroo, whose tail assists as a third foot and as a weapon of defence, there is not, in the whole of the mammalia, a tail of anything like the efficiency of that possessed by those American quadrumana. In some of the species it is longer than the whole body, and yet the bodies are of a very lengthened form in proportion to the size or weight. A considerable portion of the tail toward the extremity is covered with naked skin on the under side, very similar to that with which the prehensile paws have the palms and undersides of the fingers covered. The animals which are furnished with this appendage, have all the limbs exceedingly long, the joints with very loose and varied motions, and the whole frame supple, so that it readily bends in any direction. The hands, or climbing paws, are less perfectly formed than those of the apes which have no prehensile tail, and especially those which have no tail at all, but which depend entirely on the feet both for the extent and the direction of their motions. On the ground they are very helpless animals, and they are more helpless in appearance than they are in reality. But the rapidity with which they can ascend a tree, and the distance to which they can swing themselves from one tree to another, are both much greater than one would suppose, from the apparent feebleness of the animals upon the ground. It signifies little in what direction the motion is taken, or which end of the animal is made the point of rest, and which is ready to seize the new support. They can catch hold with the tail, swing till they have got the requisite momentum, and then project themselves till they can lay hold of a branch, and if the next branch is at a distance, they can swing again upon the fore leg, and project themselves so as to lay hold with the tail. In this way they tumble about with astonishing rapidity, and apparently often for mere sport. There are many species of them, differing a little from each other in many particulars, but all agreeing in the use of this prehensile instrument. Under the article *ATRES* will be found figures and descriptions of two of the most remarkable of the long-legged species, and we shall here

present a figure of another, of which the limbs are not so long, but the tail is perhaps longer in proportion; and in order to convey some idea of the action of these animals we have represented it in the action of swinging by the tail.

This species, and several others of the section to which it belongs, are remarkable for the loud and disagreeable sound of their voices. The bone of the tongue in many of the quadrumana is far more produced than in the human subject; and it is furnished with a large cavity or sac, by means of which, as it is understood, these creatures are enabled to produce that loud and dismal voice from which they obtain the popular name of howlers. In them there are five fingers on all the paws, but the thumbs even of the anterior extremities have very little freedom of motion, so that their principal mode of grasping is with the paw itself like a hook. Others again, the very long-legged ones to which we have alluded above, have the thumbs of the fore paws concealed under the skin, and incapable of any kind of action against the fingers.

To these succeed others which have the tails long, but not prehensile, and the fingers furnished with crooked claws, instead of flat nails like those possessed by the more characteristic hand climbers. These last approach the squirrels in their style of motion among the branches, holding on partly by the grasp of the fingers and partly by the points of the claws, while the tail, which is covered with soft and rather long hair for the whole of its length, and which though not prehensile is very muscular, is understood to serve as a parachute, which is the purpose of the produced tails of all the climbing animals which have not perfect grasping paws, or extensible skin, to assist them in their motions from branch to branch.

It would, however, be impossible to notice in a general sketch of the mammalia all the varieties of the hand or grasping paw at the extremity of the leg as a climbing organ. In proportion as the food of the animals ceases to be wholly or chiefly of a vegetable nature, the paws begin to assume a compound character, retaining still the power of grasping, and often having a thumb free in its articulation, but not acting directly against the fingers, sometimes having a mere tubercle against which the fingers act when

bent, and gradually passing into a sort of termination to the foot, resembling that of birds in a slight degree, as we find in the squirrels, and in some of the marsupial animals of New Holland which are inhabitants of trees, and furnished with extensible membranes, which act as parachutes in breaking their fall. All those membranes which are used for this purpose are to be understood as really belonging to the organs of climbing, though they are vulgarly termed organs of flying. There are no means of a flying action in any animal which has those membranes, whether broad or narrow, extending nearly from the fore leg to the hind, and leaving the foot of the former as well as that of the latter entirely free, so that each of them is still efficient both for walking and for climbing. There is no flying membrane among the mammalia, except one which stretches on the produced bones of the fore feet, and has the shoulder joints articulated something in the manner of those of a bird. This is the character of the bats, of which we have already spoken, and other than them there are no known mammalia which possess it.

Animals which have those membranes of the parachute character generally have the feet well constructed for climbing, though they climb by holding on with the points of the claws acting towards the centre of the foot, and thus in so far against each other. They are also, generally speaking, broad and flat in their bodies, and covered with a profusion of long hair, so that the weight is but small in proportion to the apparent bulk. They are also very agile animals, and capable of a good deal of motion without being fatigued. Our present concern is with their means of climbing, however; for though there is no power of upward motion in these membranes, but on the contrary the animal must sink below the direction in which it originally takes its spring, yet they prevent it from falling so low as it otherwise would do, which is at all events an indirect method of raising it. Animals of this kind are also all inhabitants of trees; and one principal purpose which the produced membranes, in large tail and lengthened fur answers, is that of enabling it to pass from tree to tree, or from branch to branch, without the necessity of descending and climbing up again by the help of the feet, which would be a much more severe labour. In ordinary cases, such as in the thick trees which our common squirrels inhabit, much production of membrane is not necessary, because the leap is sufficient upon ordinary occasions; but when the trees are farther apart, the membranes are turned to account. The following figure will give an idea of the

attitude of a climbing animal, using its membranes as a parachute; and further particulars will be found in the articles *RODENTIA* and *SQUIRREL*.

A considerable number of the ground rodentia, such as many of the rats and others, have the feet formed so as to act partially as organs of climbing; and the mode of their action does not differ greatly from the action of the feet of squirrels, independently of the membranes and other produced appendages of the latter. It is therefore not necessary to give a particular account of them as distinct modifications of the climbing foot, neither is it necessary to notice the feet of various small nocturnal animals of prey which are to be met with chiefly in the south-east of Asia, because their feet are also constructed upon nearly the same principle, only modified according to the kind of footing which they generally have, and the rate at which they move.

The climbing of bears is, however, so peculiar a modification of this species of action, that we cannot with propriety pass it without some notice. Bears may be said to have three climbing organisations, or more strictly three modifications of the same climbing organs. They climb by hugging the object which they ascend between the fore legs, if that object is a tree, or any thing which they can embrace with the stretch of their ample legs and paws. They also climb by holding on with the claws, and indeed the claws of the hind feet are the points of support, by means of which they hold their place on the trunk of a smooth tree, while they advance the fore feet in the hugging operation. The claws of the fore feet are also of some use in climbing; but they are of much less than the feet themselves, for these can be converted into most efficient hooks, by means of which the animal, even though a very heavy one, can ascend very rapidly if there are inequalities upon which these strong hooks can lay hold. The "Bear and rugged Staff" have long been associated together, and the association is not one of those fanciful ones which have, in many instances, arisen from the corruption of language; for a staff, or rather pole of that description, is the kind of ladder by means of which a bear can climb with the greatest ease and rapidity. The plantigrade form of the feet also gives the bear a great advantage in climbing as it enables him to stand on a comparatively narrow base, and raise himself up till he gets a fresh hold with the paws. When a bear-pit is furnished with poles of the proper form, the climbing of the bears, the ease with which they balance themselves on the tops of the poles, and the rapidity with which they can descend, hugging the pole all the way, are no bad specimens of the mechanical action of animals.

Climbing is not confined to those bears which are more exclusively inhabitants of the forests; for they exercise it in every locality which they inhabit. The polar bear very speedily gets from the water upon the ice, even although that ice floats at a considerable height above the surface; and when on the ice, and wishing to "scent" the horizon for the direction in which prey is to be found, he very speedily gains the top of the hummock which suits his purpose. Neither he nor indeed any of the bears can climb up a surface which is perpendicular, or very nearly so, and does not afford holds for the single paws as hooks, or for the two in hugging; but if these are furnished, this bear is a sure, though not an elegant, climber.

In all the localities which bears inhabit, in a state of nature, climbing may indeed be regarded as a necessary part of their economy. They are not, in any part of the world, inhabitants of the open plains,

though they occasionally traverse them. Their march is more rapid, and they can continue it longer, than one would readily suppose; but still they are not well adapted for giving chase, even when they seek for animal food; and their subsistence is often wild honey, and fruits, and other succulent vegetable matters, which they can procure only by climbing. Woods and places with rough and rocky surfaces are, therefore, their proper localities; and their peculiar organisation enables them to climb the rock and the tree with equal ease, which is beyond the power of the handed or grasping animals, whose chief locality is in the forest, and the only pathway on which they are quite at home is the branches.

Some particulars of the Indian species will be found in the article BEAR; but we may mention here, for the sake of illustrating the climbing powers of these animals, that the jungle bear, the Malay bear, and probably some other species or varieties which inhabit that paradise of succulent fruits—the south-east of Asia, and the adjacent isles, live habitually on fruits, for which they have to climb, and that often to a considerable height. Nor do they merely ascend and pull what they want, for they can reach the fruit of a lofty palm, and break the shell, or they can get to the more central bud, bite it off, and extract the copious supply of sweet juice which flows from the wound. This habitual feeding upon sweets is said to affect them with a greater loss of teeth than is known among the average of the mammalia in a wild state. The feats of these bears in climbing are different in character from those of the handed animals, but they equally entitle them to the character of climbers; and although, in common language, the bear is usually taken as the very model of clumsiness, yet when we come to examine his organisation and his action, we find that he is an animal of no ordinary resources, and that there are none of the mammalia better fitted for holding their place and playing their part in the grand system of nature.

The bear may in fact be considered as the typical animal of climbers of one class, as the ape is the typical animal of another. All the plantigrade mammalia are climbers to some extent or other; and it is obvious to accommodate this climbing habit that they are plantigrade. For mere walking this would be a disadvantage, because a plantigrade motion is slower and performed with more difficulty than a motion on the toes. To have given these, which are chiefly predatory animals, a worse walking motion than others have, without any compensation for it, would have been contrary to all that we meet with in the rest of nature; and this alone is sufficient to lead us to the conclusion that they have some other office to perform with their feet.

Advantage, though given to each in a different way, is yet given so equally to all animals that if we find any animal worse adapted than another for the performance of any one function, we may be certain that the one which is less adapted for that particular function is capable of some other function which can counterbalance the deficiency; and this is our grand inducement to find out the additional one. This equality of endowment possessed by all the living children of nature, taken on the average of their several species, is one of the greatest encouragements and helps to all who wish to study nature.

We shall not enumerate all the modifications of the climbing habit of the plantigrade mammalia. None of them possesses the same power of hugging

with the fore legs as the bear, but the general manner is the same; and this is the compensation for the inferiority of their walking motion as being plantigrade; in like manner as the climbing of the quadrupeds and the flying of the bats are their compensations for the same; and in all the three, the deficiency on the one hand and the compensation on the other are in proportion, and balanced with the greatest nicety. The annexed sketch will show the position of the paws in bears and other plantigrade mammalia, when they hold on or climb by means of these as hooks.

We shall mention only another modification of the climbing organs of mammalia, namely the form in which they appear in the sloths. The organisation of the limbs of these animals is such that they cannot walk, except at an exceedingly slow and crawling pace, and with the utmost fatigue and difficulty. They do not make their way readily along the upper side of a horizontal or sloping branch, and they climb the upright trunk of a tree very slowly. In all situations indeed in which the weight of the body is supported from below, their powers of locomotion work to a disadvantage, and are cramped and effectless.

Sloths are in fact the reverse of all other mammalia, in respect of the position in which they have the most easy repose and the most vigorous action. Other mammalia sleep with the belly, or at any rate the side, to the ground; and the natural position of action in all the rest, whether that action is in the air, in the water, on trees, on the ground, or under the ground, is with the back uppermost. Some of the climbers can indeed move along the under side of a branch, or at all events hold on in that position; but it is unnatural to them, they cannot continue in it for any length of time, and, if they were to get asleep, they would inevitably tumble to the ground. Not so with sloths, for their whole organisation is so well adapted for maintaining them firmly in this reverse position, that it is the only one in which they can be said to be perfectly stable. Their feet are formed as hooks, by which the weight of the body is hung, and they do not answer at all for bearing it up after the manner of ordinary legs. Inhabiting higher in the trees than any other mammalia, and subsisting entirely on the leaves which are between them and the sky, their hanging position is the one in which they can have most command over their food. Even their fore feet are never used for seizing the food, or conveying it to the mouth, for their claws and toes are not adapted for grasping, unless when they are pulled against by the weight of the body. They are closed down upon the sole, not by the exertion of flexor muscles, but by elastic ligaments; and as those ligaments are more powerful than the extensor muscle, by means of which the animal moves along the branch, or from

one branch to another, they are efficient for hardly any purpose, save this very peculiar motion; and thus they are perhaps more exclusively climbing instruments than the fore feet of any other tree animal. The hind legs have the same twisting articulation as those of the tree apes, so that when they are on the ground the outer edges of the feet are points of such rest as the animal possesses there. They are necessarily very unstable points of rest; and as the animals have besides great difficulty in stretching their legs, and cannot possibly stretch them all at the same time, their progress on the ground is exceedingly slow, and performed with great apparent labour and pain. The labour and pain are, however, only apparent, not real; but the animals are gentle and timid in their dispositions; and as they have not the power of escaping from enemies, they are much alarmed, and, like all animals when alarmed, they utter plaintive cries. They have been pitied and described as helpless, and even imperfectly formed, in consequence of this want of adaptation for walking, which is vulgarly regarded as the characteristic of the mammalia. To understand their organisation aright, we must, however, look at them in their proper place; for a sloth upon the ground is just as much out of its element as a race-horse in a deep quagmire, or a hawk in the sea.

Under the article *Art* there will be found some details of the history of the three-toed sloth; and we here introduce a figure of the two-toed one, for the purpose of illustrating the mode in which these singular creatures make their way, which is always when the forests are agitated by strong winds. That the sloths do not tumble even upon such occasions, unless where the trees are actually broken by the wind, shows how well they are fitted for their place in nature.

There is reason to believe that sloths are far more numerous than is generally supposed. They inhabit the deepest forests that are known in any part of the globe, ranging from Guyana to the dry country southward of Upper Peru, and enjoy a depth both of solitude and of shade, to which there is nothing equal in any other part of the world. It is for the very fastnesses of those forests that they are adapted. The difficulty they have in descending and ascending again, necessarily stops them wherever there is an opening in the forest; while the agility of their neighbours the monkeys, adapts them better for the margins

of those openings than for the thickest parts of the forests. Those forests are in many places so exceedingly close and dark, and so frequently flooded or covered with stagnant water among the roots of the trees, that there are perhaps hardly any mammalia in them except sloths, except it be the manate in the waters. Thus we see that their curious structure, and equally curious mode of life, are given them for the wisest purposes, and that mammalia differently constructed, could not subsist in those localities which they inhabit. There is no food for any herbivorous animal of this class lower down than the dwelling of the sloths; and unless in places where there are herbivorous ones to supply food for them, there can of course be no carnivorous ones. The peccaries and other herbivorous mammalia of South America are found in the openings, and not the depths of the vast woods of that country, and therefore the jaguars and other predatory animals are found in the same. Thus, in the depths of the forests the sloths dwell in peace and safety, perhaps more so than any known race of animals. Nor must we suppose that the part which they act in nature is an unimportant one. Those luxuriant forests are places of great productiveness and plenty; and it is a law traceable through the whole of nature, that wherever productiveness is in excess, there is always provided a sufficient number of consumers for keeping it within those bounds which appear to be essential to the health and preservation of the whole. The reason of this is equally obvious and traceable through the whole of nature. Every production of nature must exercise its productive powers within certain limits, otherwise it exercises them to its own destruction. We observe in a neglected garden or field, that natural weeds first put down the cultivated plants, and then one weed puts down another, until some one gets the mastery, exterminates all the rest, and quickly follows them to oblivion. That the powers of vegetation are very great in those American forests must be admitted, but still if they were left to be overwhelmed in the ruins of their own leaves, they would perish in time; and to prevent this appears to be the principal service rendered by the sloth.

The sloths may be considered as the most lofty-inhabiting of all the tree animals, and indeed of all climbing mammalia, that is to say, if we estimate their abode from the ground immediately under them. They also approach in some of their characters the grazing ruminantia, much as they differ from these in other characters. Their feet are simply organs of locomotion, not applied, and from their structure not very applicable, to any other purpose. With them therefore we shall close our brief survey of the climbing organs of animals. There are a few other animals which can climb, as, for instance, the goats and antelopes which inhabit high and rocky mountains. These however, climb by bounding, in which the elasticity of the body comes into play, and not by grasping in any manner with the feet, which are not fitted for any such purpose; and though the animals are, in some of the species exceedingly expert in gaining heights, yet they belong to the walking animals rather than to the climbers. The few remarks which we have to offer concerning them, can therefore be introduced with more propriety and effect in our notice of these.

Organs of Walking.—All these may be considered as belonging to one general class, though there are great diversities in their forms, in the modes of using them, and also in the other purposes which

they serve, besides conveying the animals to the places where their food is found.

They may be regarded as forming three principal divisions : first, feet which serve for walking, and for hardly any other purpose ; secondly, feet which serve for walking and also for preparing a den or burrow in the earth, in which the animal shelters itself, or finds a security for its young ; and thirdly, feet which in addition to the function of walking, serve the animal as prehensile instruments in immediately seizing its prey.

The foot which performs the single function of walking, we need hardly say, performs that function better than any of the rest do, upon the obvious principle that an organ which has more than one function to perform, cannot work with its whole energy in the performance of either of them ; and thus a certain portion of the power of the animal lies idle while it is performing either the one or the other. We accordingly find that those animals which use their feet simply for walking, are larger, and also subsist on coarser food, or food which requires to be taken in larger quantities than that of animals with double functioned feet. Those which use the feet in burrowing are, generally speaking, small animals, but strong in proportion to their size. This is obviously necessary in consequence of the additional labour which they are required to perform. A common mole, for instance, is much stronger in proportion to its size than an elephant ; and the labour which it has to perform in making its way under ground is far greater than that of almost any animal which lives upon the surface without burrowing. In proportion, however, as it is better adapted for making its way through the earth, it is worse adapted for walking on the surface. An outward motion is required in the digging feet, and this is inconsistent with the best form of articulation in the legs, and also in the feet for a free forward motion in walking, with nothing but its own weight to carry. The case is similar with all other animals which are expert burrowers, for they cannot obtain that faculty except at the sacrifice of a certain portion of their power in walking.

With those animals which use the feet as prehensile instruments, the case is somewhat similar, and as these are wholly or nearly all carnivorous, it becomes necessary that they should be capable of exerting more power occasionally than they can continue to exert for any length of time. Their prey is more substantial, however, than that of any other mammalia, and thus they are able to enjoy longer intervals of repose ; their lives being made up of short and violent exertions, interspersed with much indolence. The cat tribe, more especially lions, tigers, and the other more powerful ones, afford good illustrations of what has been now stated.

Those predatory animals which course their prey, or follow it on the scent, furnish a different species of illustration. Generally speaking, they do not require that violence of temporary exertion which the others must practise, and therefore they can make more continual exertions. Their most violent exercise is that of running ; and though some of them strike down their prey with the foot, and others turn it by the motion of the head, yet none of them can be said to clutch their prey by means of their claws. They generally also have more or less of a digging or burrowing habit when in a state of

nature ; for though some of the domesticated breeds of dogs have not much tendency to burrowing, we can draw no conclusions from them with regard to the habits of dogs in a state of nature.

We might, from the mere consideration of their structure and habits, be led to conclude that mammalia which have walking feet, should be by far the most useful to man. Like him, their proper habitation in all the principal parts of their economy is on the surface of the ground. Like man too, their feet are simply walking feet, and whatever other operations they have to perform, are performed by other parts of their bodies. It is true that they walk upon four feet, while man walks only on two ; but in the grand operation of finding their subsistence, the mouth is the only instrument with which they are furnished in addition to their walking feet, and as this operation in them is from the nature of their food and its abundance, an exceedingly simple one, the mouth is quite adequate to the performance of it ; and if the food requires to be "gathered in," as is the case with that of most animals which graze, a peculiar prehensile power is given to the lip, so that that organ secures what is divided by means of the jaws. This provision is of great service to these animals, inasmuch as, in the majority of this species, they must find their food nearly on a level with the ground on which they stand, and thus it has to be carried up to the throat against the resistance of gravitation.

Mammalia of this description do not require the same resources as those which prey upon animals ; but still as the breadth of surface which they have to range is considerable, and as many of them have to move from place to place with the seasons, they have more animal sagacity than one would suppose. Indeed, as they are the animals chiefly preyed on by the more powerful carnivora, they require a considerable degree of watchfulness and resource, in order to avoid their enemies.

There is another circumstance which tends farther to adapt those animals to the use of man, and that is, the fact of their being all gregarious, or social in a state of nature. This circumstance of sociality is in a great measure the basis of domestication ; for animals which live solitary, or in single pairs in the wild state, though they may be kept in confinement, cannot be domesticated without the greatest difficulty. Even in the same genus of animals, if we find a species inhabiting by the single pair, while the other species are social, it is an almost invariable proof that this species will be far more difficult to bring into a state of domestication than the others. Among the deer, for instance, the roebuck is, of the species with which we are well acquainted, the only one which lives in single pairs apart from each other ; and the wildness of the roebuck as compared with the fallow deer, or even with the stag, is quite proverbial.

The same leading ground of domestication occurs in other animals, even in those which are predatory. The dog family, including the hyæna, may be said to be the only race of predatory animals which have been domesticated for generally useful purposes ; for the domesticated cats are kept avowedly in order that they may pursue in houses the same habits which the smaller ones of the genus pursue in wild nature ; and though they have a knowledge of persons as well as of places, at least to a certain extent, they do not evince any thing which can be called attachment to or affection for, even those who are most kind to

them. It is quite impossible to teach a cat docility by the application of the whip, and an animal of this species cannot read the expression of the human countenance, but looks on with most perfect indifference whether those who are about her be angry or pleased. When threatened, she always endeavours to escape, and if this is prevented, she shows battle in her own defence. A dog, on the other hand, not only crouches down to lick the hand which has just been chastising him, but he interprets every look, and he will fight to death in defence of his master, or even of his master's property if he gets charge of it, and has been trained to watch.

The distinction between those two races of house animals, with which every body is familiar in one or other of their varieties, is one which throws no inconsiderable light on the general principle of domestication, and the connexion which it has with the structure of the animal on which the experiment has to be tried. We have already mentioned that the fore feet of the cat family, in all its varieties, are quite as much prehensile instruments in seizing the prey as they are walking feet; the whole race too are leaping animals, which bring the elasticity of the back bone largely into play when they take their leaps; and the smaller ones which prey much upon birds, are capable of climbing trees, partly by leaping, and partly by holding on by the claws. Though they can walk, they are not therefore exclusively walking animals; and it is worthy of remark, as tending to establish the connexion between exclusively walking feet and domestication, that the hunting leopards of India which are trained for the chase, and are the only animals of the cat family which can be made available for such a purpose, have the claws only very partially retractile, and therefore not nearly so efficient clutching instruments as the claws of common cats, while there is a resemblance to the dog family in the general cast of the body of these leopards.

The dog family, in those races which are still in a state of nature, and in such of the dogs, properly so called, as have relapsed nearly to that state, are social, and they are more active and more brave than the cat family. It seems, indeed, that social animals can borrow courage from each other, much in the same manner as many soldiers stand in battle because their regiments stand, who would otherwise take to their heels; and this proves that the instinct which unites animals into packs or societies is much stronger and more intimately connected with their general nature than we would be apt to suppose. One mountain sheep will endeavour to escape by flight from the fox, whereas, if there are a considerable number, they will advance in a crescent upon him, and make him retreat, or beat him flat with repeated blows of their foreheads, if he so far forgets his native cunning as to wait till they have enclosed him.

It is not from the society of animals of their own species only that social animals, whether predatory or not, appear to derive confidence. If one meet a solitary dog on the hill, and show as much disposition to attack him as the mere demonstration of bowing down to lift up a stone, the dog will scamper off with drooping tail and all other signs of fear. If, on the other hand, a dog of the same description, or even the same dog, is with his master or with sheep, or in charge of property, he will show a disposition to repel any offered hostility; and if he approaches a remote cottage, he will come to a considerable distance

offering hostilities to a stranger. All domesticated animals show courage in the presence of human beings; and the constancy of this increase of courage, or confidence, or whatever else it may be called, from society of any kind, leaves no doubt that it is their social disposition which attaches them to their home and their herd in a state of domestication.

The foundation of the principle of taming, and the real value to which animals can be turned by man in a domestic state, are among the most useful practical points in the natural history of the mammalia. Besides the use of the flesh of animals as food, and the coverings of their bodies and appendages in the arts, it is clear that an animal can be directly useful to man only in so far as it renders his labour lighter or his condition more secure. We have already said that in the general view of the matter, the walking animal is necessarily the one which can render man the most assistance in these ways. We do not now speak of the flesh of animals, of their skins, their wool, their horns, or any other parts of their bodies as being valuable in the arts; for all these are useful only as substances, and though they are the produce of animals, they are not available for any purpose in the arts, until after they have ceased to be animate. The service we derive from them is not therefore the service of animals; and there is perhaps no animal substance used in this way for which a proper substitute might not be found in the vegetable or the mineral kingdom. The true animal service is that which, if not performed by the animal, would require, if performed at all, to be performed by man himself. Even as this service is usually estimated, there are some parts of it, and those by no means the lightest or the least important parts, which are not of a genuine animal character in the restricted and proper sense of the term. In all cases where a mechanical or chemical power, such as the motion of the wind, the fall of water, or the production and condensation of steam in an engine can be substituted for the power of animals, the application of the animal is not strictly legitimate, and though the use of it may in many such cases be unavoidable, it should seem that it is always used to a disadvantage, because only one part of it, its mere mechanical strength, is brought into play, and the sagacity of the animal, which is frequently the most valuable part of it, lies unemployed.

Thus, for instance, when a horse is applied to turn the wheel of a mill or gin, to drag a boat along a canal, or to perform any other labour along a continuous and invariable path, there comes nothing into action but the main strength of the horse; and if it be possible to substitute some mechanical power instead of the horse, it will always be better to do it, because the horse may be more advantageously employed in some other situation where his sagacity as well as his mechanical strength can be turned to account.

There is, however, a limit to even this mechanical substitution, and perhaps, for purposes of genuine economy, it is a much more narrow limit than many persons believe, more especially in an age of great mania for mechanical power, both on the part of those who make a profit not of the actual application of such power, but of the proposed application of it in the first instance, and on the part of those who ignorant of every principle and every application of mechanics, are carried away by a fond but unfounded expectation of a gambling game greater than ex-

science tells them they can make by the exercise of their proper calling.

This, however, is a question of political economy rather than of natural history, although it is one very closely connected with the usefulness of the mammalia in a state of domestication, and also with the consideration as to which of them can be made the most useful for domestic purposes. We shall not enter upon the details; but we may mention the principle for the sake of those who may be fond of turning their thoughts to such matters. It is a principle easily stated: the mechanical substitute, whatever may be its name, its form, or the means by which it is made to act, has no sagacity, it has merely the capacity of doing so much mechanical labour, which may be always reduced to a very simple standard, namely, the raising of a given weight a certain number of feet in a given time. The animal again has sagacity, and may be used to the full extent of this sagacity, as well as to that of its mechanical strength. Therefore, if no sagacity is required in the work to be done, and the continuance and quantity of the work are sufficient to cover the expense, the mechanical powers deserve the preference. On the other hand, if sagacity is required, or if the work is merely temporary, animal power is far better.

In considering what animals ought to be used in preference to others for assisting man in the performance of his labours, there are various considerations to be made. There are only two ways of applying animal power: the first is, by the weight of the animal acting at the end of a lever, or along the circumference of a wheel, which is nothing more than a succession of levers. An animal of some sagacity is required for this purpose, because it must continue going always in the same direction. The turn-spit dog is an example of this kind, though one which it is now rare to meet with in use. The dog attempts to climb a series of steps in the inside of the ring of a wheel; and if the wheel is of a diameter properly adjusted to his weight, his weight makes him descend just as fast as he ascends; and thus while he turns the wheel he remains at the same relative point in space, the wheel gliding away from under him as he endeavours to advance. This is well, and also witily expressed by the poet:—

“ — a dog that turns a spit,
Bestirs himself, and plies his feet
To mount the wheel, but all in vain—
His own weight brings him down again.”

Dogs are almost the only animals which have sufficient sagacity for being employed in this way; but they are not unfrequently employed to turn light machinery, in cases where the work required to be done is too limited for requiring a greater and more expensive power. The tread-mill which is now used as a species of hard labour for human delinquents, acts upon the very same principle as the dog-wheel: but the parties sent there are compelled to work, from the injury that they would receive by the wheel if they did not get upon the steps.

The second mode of applying the power of animals to useful purposes is that which takes advantage of their powers of locomotion, and considers the resistance which they can overcome when moving at a certain rate without injury to themselves, though the last consideration is sometimes neglected in a manner disgraceful to the feelings, and not very conducive to the pecuniary interests of the parties. This, though

to a considerable extent it involves the structure of the animal, and the form of its organs of locomotion is, in the details, a matter of practical mechanics, having little to do with the natural history of animals, and not a very great deal with the mechanics of their structures; for it forms no part of the study of the animal in a state of free nature, but is merely an application by man of the power of the domesticated animal.

Moving a load or quantity of matter from one place to another, either by carrying it, or by pulling it, are the chief forms of this mode of applying animal power, and as it is the only one in which the power of animals is at all extensively employed, it is the one which deserves the chief attention.

In this respect there are necessarily a great many differences, arising from the nature of the work which the animal has to perform, and the character of the ground over which it has to move; and much of the decision in this case must necessarily depend upon the structure of the animal's feet. The feet of working animals are of two kinds, feet with toes and feet with hoofs, and the latter are either single, or consist of two real ones, on which the animal walks. In addition to these it is necessary to include the elephants and the camels, whose feet are not, strictly speaking, of either class. The feet of the camel are adapted for travelling over dry and sandy surfaces, and those of the elephant suit better with soft ground which is covered with rank herbage. The feet of the camel have only two toes, furnished with nails rather than with hoofs, which are united on the under side, and the sole of the foot is covered with a soft pad, which is equally ill-adapted for hard or stony substances and for humid ones. Accustomed to traverse the sandy deserts, in quest of the hard and scanty vegetation upon which it subsists, the camel lifts its feet straight up, in order to clear the sand. Its march is thus exceedingly dodging, and camel-riding is no very agreeable exercise for those who are unaccustomed to it. It is this high lifting of the feet, and consequent planting of them down with the weight of the body ramming them against the ground, which disqualify the camel for walking with ease on the surfaces which we have mentioned. This jars the leg, shakes the body, and pains the sole of the foot when on a hard pavement; and it is painful to look at a camel when led through the streets of one of our towns, where it has to tread upon unyielding granite. This is most remarkably the case with the dromedary or single humped camel, which is more feeble than the one with the two humps, and also lifts its feet proportionally higher. The same circumstances which enable the two humped or Bactrian camel to travel more easily over hard surfaces than the dromedary enable it to do so over humid surfaces, and thus it is useful over a greater range of country than the other.

Still camels are useful only as beasts of burden, and for long marches they are expensive animals. Their pace, besides its jolting character already described, is but slow, and the pain with which they walk over hard surfaces, renders them of no use whatever for draught. They are in fact fit only for countries which are in great part deserts; and in proportion as mankind inhabit more closely together, and have more of the accommodations of civilised life, camels become less and less useful to them.

Elephants are animals of great strength, and capable of supporting, and occasionally of drawing, very heavy

weights. They cannot, however, be profitably reared in a domesticated state, and therefore the use of them is necessarily restricted to a very limited space in the vicinity of their native forests. In the peculiar style of walking, both of camels and of elephants, at their usual moderate pace, at which they can continue for a considerable time without rest, we see examples of one of the disqualifications for labour in animals which are not deficient either in size or in strength. It will readily be understood that every motion which deflects the centre of gravity of the body of an animal from the straight line of its march, whether the deflection be right and left or up and down, increases the labour of the animal by the burden of its own weight carried over the whole measures of those deflections. Thus for instance, if the step of a camel in its slow march is two feet and a half (the actual measure is a matter of no consequence), and the dodging raises the centre of gravity three inches at the one part of the step, and moves it three inches laterally in the other part, then in addition to the step of thirty inches it has carried its own body six inches in absolute space, and the straining and new momentum necessary to be acquired at every turn may be reckoned at four inches more. By means of this constant moving of the centre of gravity, therefore, such an animal must exert one-third more strength in order to get over the ground than an animal which carries the centre of gravity forward in a direct line. The loss must be the same in the case of the load which it carries as in that of its own body; and therefore, even as beasts of burden, camels work at a very great disadvantage, both in respect of their own bodies and in that of the burdens which they can carry. The disadvantages in the case of the elephant are probably not less, but the great strength of the elephant, and the fact of its being employed chiefly in cases where show is the object rather than economy, do not bring it within the limits of ordinary calculation.

None of the toed animals are of sufficient size for being employed as beasts of burden, or for purposes of draught, except for very light weights, or in such numbers as to be inconvenient in thickly inhabited countries. Dogs are indeed used for drawing trucks and other light carriages, and they are the animals exclusively made use of by the Esquimaux for drawing their sledges over the snow. They are much more hardy and less subject to fatigue than almost any other animals; and at their common walking or running pace, in which the elasticity of the spine does not come into action, they are well formed for such weights as they are able to draw. When they run, however, they jerk the body so much up and down by the action of the spine that they are inefficient in short harness. When yoked by long thongs, as the Esquimaux yoke them, they are more effective when put to their speed; but then the difficulty of getting them to pull together more than counterbalances the advantages derived from the freedom of their action; and the loss of power in this way renders it necessary to employ more than double the number that would be requisite if they could pull fairly together. We cannot, however, consider the employment of the dog generally as a working animal, as the most economical use of them. The leading character of the dog, taken in the average of the breeds, is not his physical strength, but his courage and sagacity taken jointly; and when he is made a merely mechanical labourer, what ought to be

considered as his most valuable properties are left unemployed.

Our field of examination, as to the advantages of the mammalia for mere labour in the service of man, is therefore narrowed to the hoofed animals, and even for general purposes to a few of them. The solid hoof is preferable, as a general base from which to overcome a resistance in traction, to the divided hoof, although as the divided hoof takes a firmer hold on its support, there are some cases in which it deserves the preference.

Of solid-hoofed animals the horse possesses advantages over every other, in beauty of form, in steadiness to the line of motion in most of his paces, and in fitness for every description of climate; and of the animals with divided hoofs the preference must be given to the ox tribe, in their superior strength, docility of manners, and adaptation to climate. We need not go into any details of either of those animals, because every reader has opportunities of observing them for himself. Whoever chooses to observe will perceive that in all the paces of a well-bred horse there is very little swing of the centre of gravity, and that the principal motions are performed by the limbs, and not by the spine. In slow motion the centre of gravity in the ox is also steady, and therefore an ox can take a strong pull in comparison to his weight and strength. Such animals are, however, not well adapted for rapid motion, and consequently their chief use is in the labour of the field, or in the bearing of burdens along difficult roads, in the latter of which respects they are not equal to mules, either in sure-footedness or in patience of endurance, and consequently wherever mules can be procured for roads which are too difficult for horses they are preferred. Mules of superior quality cannot be obtained, however, except in comparatively warm countries, because the ass degenerates much more from severity of climate than the horse does, and the good qualities of the mule appear to depend much more on those of the ass than on those of the horse. Among the hoofed animals there is a modification of the style of walking, and consequently of their organisation as adapted to that style, which is worthy of notice, namely, the difference between galloping animals and leaping or bounding ones. Goats, sheep, and antelopes, and also deer, are all bounding animals—that is, they can throw themselves to a considerable height from the ground, and project themselves to a considerable distance. Such motion is perfectly incompatible with the carrying of riders or burdens, or with drawing in short harness, and therefore none of the animals are used for any such purposes. These naturally, therefore, are left more in a state of nature, or sought for only on account of the substance of their bodies, than the races which have not this bounding style in their rapid motion. The only exception worth notice is the rein deer, which is so effective in drawing the sledges of the Laplanders, and that animal draws in comparatively long traces, and could be but little effective in applying its weight to the rapid traction of a vehicle with shafts.

Organs of Leaping.—The last mentioned ruminant animals, which bound along with incredible swiftness, and rise high and project themselves far in some of the species, are, notwithstanding their agility, and the splendid style of their motions, not strictly speaking leaping animals. Their anterior and posterior extremities are nearly of the same length; and though

they always deliver themselves in leaping from the hofs of the hind feet, they receive the whole weight of the body upon the fore ones, which support it until the hind feet are brought up, as the points from which to take a fresh leap. This is often done with so much rapidity, and the body projected to so great a distance, that we cannot observe the bringing up of the hind feet, or the rest upon the fore ones, while this is performing; but whenever we see an animal in this kind of action, it appears always to have the fore feet at full stretch in advance, and the hind ones equally so in the rear, and our conception is that it trips along upon the points of the hofs, without any flexure of the legs. This however is not the case, for all the joints of the legs, the muscles of the shoulders and haunches, and partially also the spine, are brought into equally violent and rapid action in this magnificent style of progressive motion. The spine, indeed, has but little flexibility in such animals, because a flexible spine would shorten the leap; but still in as far as it admits of change of flexure, the spine of these animals comes as much into action during their violent motions as any other part of their body. This bounding motion is therefore only a higher style of galloping than that practised by such an animal as the racehorse; and when an antelope bounds over the lofty bushes, its action does not differ in kind from that of a hunter when he clears a hedge or takes a lofty gate.

The leaping animals, properly so called, walk with difficulty and a hopping motion, even when their pace is at the utmost, and never exhibit the steady straight-forward pace of the true walkers.

The leaping animals among the placental mammalia almost all belong to the order *Rodentia*, or the gnawing animals. To these must be added the kangaroo among marsupial animals, which are the most characteristic leapers among the whole, as well as the largest in size.

The placental leapers belong to three distinct genera, of which, however, it is unnecessary to give a particular account here. The first and least effective are the hares, which run rather than leap, at least as standing erect on the hind legs, and they differ from the others in having the tail exceedingly short, and of comparatively no use either in directing their motion or assisting to support them when they move. The following cut will furnish an idea of the position of the hare when moving up hill, the kind of ground upon which her motions are by far the most effective.

It will be seen from the cut that the fore legs are very short and slender; as compared with the hind ones, which last are the chief organs of motion; the bound taken upon them extending at least three times as far as any that could be taken on the fore legs.

When the long hind legs are brought forward, the rump is greatly elevated compared with what it is when they are stretched out; and this is the reason why a hare when running appears to be constantly elevating the white or under part of the tail. It is unnecessary to enter into any further particulars of the motions of the hare, because it is an animal with which every body is very familiar; we may mention, however, that from the kind of food on which they have sometimes to subsist, and the way in which they have to arrive at it, hares have sometimes to use their feet as a sort of imperfect hands, that is, they have not only to bring them to their mouth in feeding, but to use them in climbing up to gnaw the bark of bushes and young trees, at the season when there is no other food for them in the fields; in order that they may have the cross motion of the fore feet necessary for bringing them to the mouth, they have some sort of point of support to prevent the shoulders from approaching each other, and thus defeating the grasping motion; and this is done by means of imperfect clavicles. Perfect clavicles are necessary for the performance of a perfect cross motion; but as with the hare such a motion is only occasional, the clavicles are not complete, and thus they do not interfere so much with the running of the animal as they would do if perfect.

The next gradation of leapers are the small animals vulgarly known by the name of jumping hares (*Pedetes*). Only one species of this animal is known. It is a native of Southern Africa, about the size of a rabbit, and burrows deeply in the ground. Its fore feet, which are very well formed as compared with the hind ones, have five toes; and it uses them both as hands in conveying the food to the mouth, and in digging the burrows which it inhabits. It is a nocturnal animal, and during the dry season it has to find its food by reaching upwards. Many of the mice have this property to a considerable extent.

The third, and perhaps the most expert leapers among placental mammalia, are the jerboas properly so called, of which there are several species, inhabitants of the dry countries in Northern Africa and Western Central Asia. In them the fore legs are so short in proportion to the hind ones, that they are rarely brought to the ground when the animal walks. The deficiency of the fore legs is to a great extent supplied by the size of the tail, which is longer than the body of the animal, and which serves to balance it in an upright position as it jumps along, springing from and alighting on the hind feet, the soles of which are provided with very large pads by which its fall is broken.

The tail of the jerboa is merely a balancing instrument, and it possesses no great muscular power, all the vertebræ of that organ being long and slender, and destitute of any processes to which powerful muscles could be attached. It has therefore less motion than the tails of many animals, which are far shorter. From the point of its insertion being so far from the ground, it derives, however, a considerable lever power; and as the animal folds its short fore legs down on the breast when it leaps, and holds the body in nearly an erect position, the hind feet come to the ground again, almost directly under the centre of gravity; reckoning from the articulations of the thigh bones, the hind legs are at least six times the length of the fore ones; and there is a peculiar formation in the central part of the hind foot, which, inde-

pendently of the pads with which the soles are provided, gives the animal great firmness as well as concentration on these feet. Some of the family have only three toes upon them, and some have five; but in the latter the two lateral toes are so little produced that they do not contribute much to the size of the foot. In order to give the requisite firmness, the metatarsal bones are very much produced, and united into a single piece as far as the three principal toes are concerned, thus forming a true canon bone, the same as is found in the feet of animals which are characteristically walkers. The hind feet are thus walking feet of the very best description; and they are so large and strong in proportion to the fore part of the body of the animal, that they make no bad substitute for all the four feet of animals which use the fore ones as well as the hind for no other purpose but that of walking. In consequence of the elasticity, the jerboa, though comparatively a small animal, can easily jump to the distance of five or six feet; and it sometimes takes its spring from the toes only, and sometimes from the entire sole of the foot. The latter affords the most vigorous leap, from the velocity with which the rapid unbending of the ankle-joint propels the animal in an upward direction.

The most characteristic of the leaping animals, however, is the kangaroo. Opportunities now occur at almost every zoological collection, especially those in ample gardens, where the animals can display their natural action much better than they could possibly have done in the old-fashioned places where they had scarcely room to stretch themselves; but still even in these places the manners of an animal so peculiar in its form and its action, and also in the localities which it inhabits, cannot be seen to their proper advantage. The annexed cut will furnish some idea of it, both in its reposing and in its leaping attitude; and the reposing one, being nearer in the representation, and therefore on a larger scale, may

be regarded as a very faithful portrait of the animal. It will be seen from both figures that the fore legs are exceedingly small; and that the body of the animal tapers, from the setting on of the hind legs, all the way to the extremity of the nose. But though the fore legs are very small, the extremities of them

are very well made out. They are each furnished with five toes having a free motion, and armed with claws very strong in proportion to the size of the members themselves, only the two lateral ones are considerably shorter than the rest. The elbow-joints have very free motion, so that the fore arm can perform a complete revolution, or rather rotation, in the articulation of the radius. The hind legs, though much more produced and powerful than the fore ones, have not the toes on them so well developed. The whole strength of that part of the foot is thrown upon a single bone in the metatarsus, as in the jerboas; but this bone does not consist of three bones soldered together as in them, it consists of one bone supporting one toe. This bone is remarkable for its size, the toe is very strong, and instead of a claw it is furnished with a true hoof of large dimensions at the extremity. In consequence of this, when the kangaroo springs from the hind feet, it springs from one principal point of support in each, in the same manner as the single hoofed animals. The feet contain other three toes, much shorter and feeble than the middle one; so that, though they assist in preserving the balance of the animal when it has the whole length of the tarsus upon the ground, they do not interfere with the free action of the central and powerful toe when the animal leaps. In their bones those three toes make only two; for the two internal ones are completely united, with the exception of being furnished with two claws, which are not hoofs like those on the middle ones. These lateral claws are long, but they are very feeble as compared with the middle one; they are metatarsal bones, having little more than the one hundred and fiftieth part of its section, and consequently of its strength. There is not so remarkable a difference between the strength of the bones of the toes, in any other known genus of living mammalia; and indeed in as far as efficiency, when the animal is on the toes, is concerned, they serve little other purpose than the small hoofs, behind the principal ones, with which animals which divide the hoof are generally speaking supplied. This great enlargement of the central toe, and corresponding reduction of the others, is a striking proof that concentration is a most essential requisite in those extremities from which an animal is to take powerful leaps. The tail of the kangaroo is a still more efficient organ of balancing than that of the jerboas; and, as will be seen upon looking back at the figures, no other of the mammalia is provided with a tail of equal weight and strength; in volume it is scarcely less than the entire body, anterior of the portion which is supported directly by the hind legs; and therefore the animal has its centre of gravity very near the articulations of the thigh bones. The internal structure of the tail indicates as powerful an action in that organ as its form and size indicate weight. The vertebrae of which it is composed are provided with numerous and well developed processes for giving origin and insertion to a vast number of muscles; and the power of the tail, both in the firmness of any position which it assumes, and the rapidity with which it changes from one position to another, gives it very nearly the efficiency of a third foot, whether in supporting the animal, in enabling it to balance itself, or change its direction, or in being used as a weapon against an enemy by which it may be pursued. It is reported indeed that when the kangaroo is chased by the wild dogs of Australia, or by the dogs of the colonists, it does not stand up and take the tremen-

does leaps which it does when ranging its pastures, but runs on all fours something after the manner of a hare, so that it has always the tail ready to strike the enemy when that enemy comes near. The march of the kangaroo, and its organs of marching, are really unique among the mammalia; and it is impossible to associate it closely with any other animal, whether marsupial or not. The tail of the beaver is perhaps the one that comes nearest to it in dimensions; but that is a swimming tail, or if it has any other appropriate function it consists in supporting or propping up the animal, when in the act of constructing or repairing its curious dwelling. In the length of their posterior extremities as compared with the anterior ones, and also in the length of their tails, the jerboas approximate the kangaroos; but in their mode of action they are altogether different; and though they too are very different in their forms from the mammalia with which we are more familiar, they still leave the kangaroo alone in its peculiarity.

Those which we have noticed are the most remarkable of the leaping animals; and, with the exception of hares, which, with some slight differences, are found in most parts of the world, except the locality of the kangaroo, they are all confined to places resembling each other in their physical characters. The regions which they inhabit are not exactly barren; but they consist of deserts for the greater part, with only a patch of vegetation here and there. The leaping enables the animals to clear those sandy spots which they must pass, but which are too loose in their texture for bearing the tread of even such comparatively small animals as the jerboas. They are thus enabled to subsist in pastures which could maintain no other animals; and in the case of the kangaroo, which is far larger than the others, there is a considerable range in the way of food; for though the principal subsistence is vegetable, the animal can eat animal food in case of necessity; and it is by no means unprovided with weapons for killing its prey, in case living prey should come in its way and be necessary. In this respect it has some slight resemblance to the bears, which are vegetable feeders in the main, though they occasionally resort to animal food. It has not indeed the terrible hug of the more powerful bears; but still it can keep a firm hold with its fore legs, and the hoof on the hind foot is a far more murderous weapon in wounding than the claws on the hind foot of the bear, and it is used nearly in the same manner.

Digging or Burrowing Organs.—We have already made some allusion to the structure of foot best adapted for making way under ground, in speaking of the common mole; and we resume the subject now only for the purpose of pointing out what particular habits of animals are connected with the possession of feet adapted for this purpose. They belong to several of the order of mammalia, as arranged according to their internal organisation, by which is meant more exclusively the system of nutrition than any other part of the animal, or than the whole structure of the animal, as indicating a disposition, or rather adaptation, for the performance of certain kinds of action more than others. We shall have occasion briefly to advert to the principles of this method of arrangement in a future section, but we may now mention that the grand distinctions are founded upon the nature of the food; and as the different kinds of food are found in different localities, the adaptation of the animal to the locality where its food is princi-

pally to be found, follows as a matter of course, upon that general principle, that all the provisions of nature are the very best, in respect both of maximum of accomplishment, and minimum of exertion required for that accomplishment.

The three divisions dependent upon food are, warm-blooded or vertebrated animals; invertebrated animals, generally expressed under the name insects, though these form only one class of the grand division; and vegetable substances, which include almost every part of vegetable bodies, from soft pulpy fruits to dry wood. With the exception of a very limited number of invertebrated animals, some of them permanently and some only in certain stages of their changeable being, there are no animals which live under the surface of the ground; and therefore we may be prepared to expect that the insectivorous mammalia, who have their habitual dwellings, and find the whole of their food there, must be but few in number. There are, however, many insects, especially in countries of ardent climate and great fertility, which make their dwellings under ground, or construct them immediately upon the surface, though they find their food above the surface. It is not our present province to enter into the details of those animals; but we may mention that the majority of them, though not the whole, are consumers of decaying vegetable matter, and perform the same office in nature as animals, that the fungi do as vegetables. Those creatures exist in numbers beyond all arithmetic, and even all imagination, and in most situations where they are found the use of them is seasonal. There must therefore be, according to the general law of nature, which is that the waste of every species tends to the destruction of that species, if not removed by being applied to some new purpose of usefulness, a corresponding provision of animals to prey upon and regulate the myriads of those creatures. For this purpose, ground animals are required; and both their protection from enemies and from the heat of the day, and their means of arriving readily at their food, require that they should be burrowing animals, or possessed of feet adapted for digging into the ground. During the day the prey of those animals is, generally speaking, scattered abroad; and this renders it necessary that the animals themselves should be night preyers. In the countries where those animals abound the most, the difference of temperature between the night and the day is greater than in more temperate climates, and day and night are much more nearly upon an equality throughout the year. Exposure to great differences of temperature is one of the severest trials to which the animal system can be subjected; and as the animals of which we are speaking do not require to feed or make any other exertion during the heat of the day, it would be subjecting them to useless waste of the system, and thus contrary to that wisdom which pervades all nature, to have them exposed to the ardent heat of the sun. To avoid this they are almost without exception adapted for digging burrows, in which they may pass their time during the heat, though of course the natural instinct which leads them to dig the burrow, leads them also to avail themselves of any natural hole or crevice, which will afford them that shelter in which they may not feel the painful sensations produced by exposure to the air. For this reason, we find that a foot adapted for digging is very general among insectivorous mammalia, whether they belong to one order or another in the systematic arrangement.

Vegetables, generally speaking, grow partly in the earth and partly in the air over it; and in those vegetables which have annual stems in the air but roots in the earth, lasting for more than one year, the part in the earth is the only existing part at some seasons, and the most succulent part; and therefore the most nutritious food for animals at all seasons; unless when a particular portion of the root has brought its annual stem, its flower, and its seeds to maturity, and thus, having performed its grand function in nature's economy, is completely exhausted, and its remains pass to the general store of inorganic matter, without any assistance from a preying animal. In warm countries especially, and in all countries where the great alternation of the seasons is wet and dry, there is a necessary perishing of annual surface vegetation, unless in those succulent plants which, from the peculiar texture of their covering, are proof against the action of heat; and even in them the flowers, flowering stems, and all other parts immediately conducive to the annual production of seeds, are subject to the same fate. In such countries the drought penetrates to a far greater depth, and scorches and withers with far more severity, than it does even in those long continued courses of dry weather which leave our pastures without a blade of grass. Therefore, in such countries, the herbaceous plant must be provided for in a manner corresponding to the severity to which it is exposed. This is effected by a bulb or tuber of some description or other, sometimes seated above ground, sometimes placed under it, and sometimes partly the one and partly the other; and from the nature of the case, it must partake more or less of the properties of the succulent plant, which endures the ardours of a tropical sun upon the surface during the dry season, according as it is more or less exposed.

Here again there is an ample store provided for those mammalia which feed upon succulent vegetables, and this store requires a digging foot, in order that it may be arrived at with the least labour by the animals which subsist upon it. But in the dry season of such countries the nether air and the surface of the earth react in consequence of the surface of the earth sinking lower in temperature than the air over it does; and the variation not being diminished to the same extent from its extending freely to the cloudless sky, this occasions a heavy fall of dew, which softens the surface, as well as makes "the scent" of those bulbs upon which the animal feed, "lie," as the sportsmen express it. Those circumstances taken together tend to render such animals nocturnal feeders; and the very same reason which makes the nocturnal feeders, formerly alluded to, burrowers, applies to those under consideration, so that even the vegetable feeders of those burnt up countries live in burrows during the day, and come abroad only during the night.

Succulent vegetable matter, such as that which is found in bulbs and tubers, and often in roots differently formed from those, while they remain in the earth, without any strong action of parts in the air, may be considered as a sort of intermediate link between the flesh of animals and the leaves of fibrous parts of plants, which have been elaborated under the influence of the atmosphere, and especially of light. We do not mean to say, that in a physiological point of view, this matter is as much akin to animal matter as to vegetable, for it is strictly vegetable matter; but when we consider it merely as the food of mammalia, or

indeed of any animals, it holds the medium place which we have assigned it. It is the same with the farinaceous part of the seeds of vegetables, which elaborated under a protection from the severe action of light, and are all pulps in the immature state, and in so far reducible to pulp again by the action of heat and moisture, without the immediate contact of the free atmosphere, and the immediate influence of the rays of the sun. This is the same whether those seeds are produced on perennial trees and shrubs, or upon annual stems, and the seeds are shed and scattered on the ground, at the very time when the annual stemmed plant, which has a root of more than one year's duration, or produces new roots every season, is down in the bulb, stemless, and in a state of comparative repose. Those seeds do not, under ordinary circumstances, get so deep under the surface as the roots do, but they fall in concealment among the remains of that vegetation which has performed its functions during the season, and is passing into decay. Those seeds are in fertile places so exceedingly numerous, that if a very large portion of them were not removed, they would have no room to vegetate, but would perish by whole races every year. The prevention of this requires a great number of small ground animals, of which the rat family may be considered as the chief; and the vast numbers in which these animals occur in almost every country under the canopy of heaven, is a proof of their high importance in the economy of nature. The jerboas already alluded to are members of this great family, and though they are the most characteristic leapers, and the most decidedly formed for the purpose of leaping, the hind legs of all are more or less provided with canon bones, and the fore legs have more or less of cross motion, and the toes well developed and free, so that they can answer partially as hands, both for conveying the food to the mouth and for grasping while the animal stands erect on the hind legs, or holding the food, until it is divided by the action of the incisive teeth, which are remarkably free, well-formed, and powerful in all such animals.

The food of this family, and the places in which they have to seek for it, point to a nocturnal habit, and the possession of digging feet, as well as those of the feeders upon ground insects and the roots of plants; and observation shows that the manners of the animals are in perfect accordance with this. During the heat of the day, or in the clear light, "there is not a mouse stirring;" and in towns rats take up their habitations by thousands in the common sewers and drainages. It is the same with the whole family; for they inhabit in darkness during the day even where they come freely abroad during the night. They are all furnished with eyes of remarkable brightness; and from this we may conclude that they see objects by far dimmer light than any animal can do, though there is no reason to suppose that even they can distinguish objects by vision in the very darkness of night. It is highly probable that scent is their most powerful sense; for we find that traps set for the capture of rats and mice must be baited with odoriferous substances; but it is also probable that their hearing is also acute. They do not require this for conducting their own labours in the finding of their food, so much as they require the sense of smelling, because their chief food does not stir or make a noise so that they could be guided to it by the ear.

As the vegetable food of all the ground feeders of nocturnal habits and with digging feet is of that kind which we have described as being considered as food intermediate between animal matter and vegetable matter, it is natural to suppose that all these animals should be more or less omnivorous, or capable of subsisting on the flesh of vertebrated animals, on that of invertebrated ones, or on vegetables; though it does not follow that they could, at least in many of the species, subsist upon green leaves or vegetable fibres; because their cheek teeth are not adapted to the preparation, or their alimentary apparatus to the digesting of these. We find that in this again we are borne out by observation in every case where our observation can be applied. Rats, and even mice, are great consumers of insects; and in some places where the lower apartments of houses are infested with cockroaches, the inhabitants find it necessary to encourage mice for the purpose of getting rid of these more destructive and far more loathsome creatures. The pulpy and farinaceous matter, upon which all the ground mammalia to which we have alluded as vegetable feeders subsist, must be considered as *vegetable fat*, that is, as holding the same place in the vegetable kingdom as fat does in the animal: that is to say, neither of them is a perfectly organised substance, but each is an assimilated matter, the one vegetable and the other animal, ready for the supply of materials of organisation, when these are either too imperfectly developed, or in a state of too much exhaustion for being capable of performing the necessary labour of assimilation for themselves. True to this correspondence between their vegetable and their animal food, those mammalia prefer fatty or partially organised substances, or substances not organised at all, to those of which the organisation is perfect. Cheese and bacon are proverbially the staple baits for a rat-trap; and mice attack these substances in the larder in preference to joints of the finest meat, nor is it probable, except in cases of extreme hunger, that any of these animals will gnaw the tough fibres of a well-organised muscle.

The structure of the digging foot with which those ground mammalia, to what order soever they belong in the system, are provided, requires no lengthened detail, and indeed no mention. To give good effect to a digging foot it must not be too long, for that would render it less effective, because the muscles having to act against a greater length of lever, would have their power proportionally diminished. On this principle the short fore-leg of the jerboa is a far better digging leg than the hind leg would be, which is six times the length, although it is just as inferior a walking one, and that from the very cause which makes it so superior for digging.

It may be worth while to notice the mechanical principle upon which this difference depends, and the adaptation of that principle to the scene of action in both cases. In the foot for rapid or powerful motion in the air, originating from a solid base, or point of resistance in the earth, the grand desideratum is velocity. The resistance of the air to the passage of any of the average size of the mammalia is but small, and from every kind of experimental knowledge which we have of substances projected from a fixed point on the earth into the air, we have reason to conclude that the range depends wholly upon the velocity. But the way to obtain velocity in the jointed limbs of an animal is to have the origin of the muscle which is

to move a distal bone, placed as far as possible, proximal of the joint, upon a long bone. This portion, taken to the centre of articulation in the joint, may be considered as one arm of the lever; and at any supposed flexure of the joint, the other arm of the lever, which represents the power of the muscle, is the perpendicular from the centre of motion at this point; and in proportion as this is less than the other, its power would be reduced in moving the distal bone. But because the muscle is in itself exactly the same in what ratio soever it is apportioned to the two bones, its power must be the same, upon the obvious principle that a quantity remains the same in its total amount into whatever ratio of parts it is divided. In consequence of this, if the power is reduced to one-tenth, the velocity will be increased ten-fold, and so on in the case of every other proportion. This is the real reason why all fleet animals have long legs, but we deferred mentioning it until we could contrast it with the reason for animals having short legs.

In the feet of a digging animal, it is strength and not velocity which is necessary; and therefore the bones require to be short, so that the lever power of the muscle may be a maximum; and in proportion as the length, from the origin upon the one bone to the joint, becomes less in proportion to the distance from the joint to the insertion on the other bone, the power of an equal muscle is increased, and the velocity with which it can move the bone diminished in the same ratio. It follows from this, that an animal, the whole of whose feet are adapted for digging, must of necessity be a slow walker, and this is the reason why, when the peculiar nature of the posture of an animal of this kind renders a quick motion along the surface necessary, the hind legs are produced to so disproportionate a length compared with the fore ones. This structure would not suit an animal which had to seek its food by perpetual burrowing under the ground; because such an animal requires a powerful action of the hind legs as well as the fore ones, and does not require a greater capacity of swift motion in the one pair than in the other. When, however, the burrowing is only an occasional operation, as that of digging a lodging in the ground, or scraping away the earth to arrive at a bulb or other root, the hind legs admit of that production which is essential for quick motion along the surface of the ground; and, as has been already observed, such animals must necessarily perform their rapid motions by leaping, and not by running or galloping. In this double adaptation of the animal, there is necessarily some waste of its whole power, just as there is waste of the whole power of a single organ, in all cases where that organ has a double function to perform. The two adaptations of the whole animal are, however, in all cases, as beautifully proportioned to the relative use which it has for the two kinds of action, as those of the single organ are adapted to the use made of its two functions. If one predominates greatly above the other, the adaptation is correspondingly great; and in proportion as the uses of them approach to an equality the adaptations do the same; so that, though a loss upon the whole is, from the very nature of the case, inseparable from a double adaptation, there is never more than the average loss in any one instance.

The same rule applies in the mechanical action of the human body, and there is a good deal of practical instruction to be derived from attending to it in that

point of view. The universality, so to speak of the human mechanism, necessarily renders man less efficient, in proportion to his general muscular strength, for some one particular kind of natural action, than any one animal with which a comparison can be instituted. The same holds good in those manual and mechanical operations which man learns from experience, as from the exercise of his mental faculties. There is perfect truth in the proverb "Jack of all trades and master of none," and this applies to every mechanical trade, whether the manipulation which it requires be simple or complex. The more simple that it is, however, the greater the practical advantage, because the same practice necessarily gives greater dexterity and expertness. If, for example, it is a single and simple mechanical operation, which does not admit of two individuals being employed at it, then the handicraft labourer may be said to work to the greatest possible advantage to which he can work; and were it possible to reduce all the manual operations in the arts to this state of the ultimate division of labour, the whole of events would derive the greatest possible advantage from the least possible exertion.

This advantage of the division of labour is not confined to merely manual operations, for it applies equally to every kind of doing, however philosophical the principle may be upon which that doing proceeds. This will be readily understood, if it is borne in mind that we derive our original knowledge of every property of material substance by the exercise of bodily sensation alone. What use we may make of this observation afterwards is quite a different matter, and has not necessarily anything to do with the acuteness of the bodily sense. It is here that the mental part of our nature takes up the subject, and by comparing the results of observations after they have become mental perceptions, discovers their relations, and the purposes or uses to which those relations may be applied. When we come to the application again, we are thrown completely upon the bodily sense and the muscular exertions of the body, which are necessary as consequences of the information of the senses as to the nature of the materials immediately under our hands. In this case, therefore, the same as in a single case of sensation, mental perception, and consequent action, it is only the middle part, or the *vinculum*, by which the other two are as it were tied together in the sequence, which is mental or intellectual, and peculiar to man and all the animated creatures of which we have any direct experience. Take away this, and leave only the sensation and the action, and man would be placed exactly on a level with the other animals; that is, both his sensation and his action would be more feeble and imperfect upon every single subject, in proportion to the greater number and variety to which they were turned.

The parallel between man and the other animals in respect to increase of power from diminution of range, goes even a good deal further than this; for it reaches the directing of others, as well as the practical management of our own affairs; and in proportion as the range in either of those cases is more limited, the efficiency with equal exertion is increased not only in respect of the individual subject of attention, but in respect of the total practical value of the exertion. It is natural, and indeed necessary, to suppose that this should be the case; for, in so far as observation unwarping by any hypothesis or theory goes, we find all animals proceed upon the same

principle, varied almost without end in the different species, but still radically and substantially the same. Man, considered as animal, is produced, grows, is nourished, and dies, exactly upon the same principle as the other mammalia; and in proportion as they resemble him in their alimentary system, they are nourished the better by the same food, injured more certainly by the same changes, and killed more certainly by the same poisons. So that, in every point of view in which man considered merely as an animal can be placed, he follows that general law which is common to all animals, and his physical advantages and disadvantages depend upon circumstances precisely similar. This perfect coincidence, in general principles, between ourselves and the other animals, in the merely animal part of our nature, is one of the most important applications that can be made of the natural history of animals, because it enables us to bring our mental powers to bear upon them, and to profit, so to speak, by their experience as well as by our own. "Go to the beasts and they shall instruct, to the fowls of heaven and they shall teach knowledge," says an authority which cannot be doubted, and we have practical demonstration of it in the proper analysis of the case. This analysis consists in a careful separation of all that portion of our progress from sensation to action which is animal, from that which is intellectual, and the general conclusion taught to us by the mammalia, which, as they resemble us the most, are our fittest instructors; and the conclusion we arrive at is this—that to this purely animal part the principle of the division of labour cannot be too constantly or too rigidly applied, and that the perfection of the profitable use of this part of our compound nature consists in dividing it down to the individual sensation and the individual act. It is true that this is a degree of perfection which cannot be arrived at, or even very closely approximated, by all the members of any community, or even by any single individual; but our imperfections do not invalidate the principle, and so the further that we can carry it in every case, the greater is our reward in proportion to the duration and severity of our labour.

But we must be on our guard against applying this conclusion to what we arrive at by the most legitimate philosophical means, respecting the one part of our compound nature, to the other part of it. The examination of one of the parts of this compound nature of man would therefore be not only imperfect, but it would be apt, and even certain, to mislead those who are not conversant with such inquiries, if it were not accompanied by some notice of at least the leading principle of the other part. Now though, according to the foundations of our judgment of matter, we have nothing but negative perceptions and consequently negative definitions of mind, those negatives enable us, though not to say what it is in itself, yet to say in what it differs from matter. The essential and inseparable property of matter which belongs to it in all its forms and in all their modifications is gravitation, or a certain tendency the action of which cannot be restrained, or turned into a different direction from the straight line joining the centres of gravity in two pieces of matter, except by the operation of some force. The quantity of this operation is all that is resolvable into two elements—time and force, of which, when they can be stated in numbers, the product is the expression for the energy of the force or power; and, as in the case of the same force or power, this

product must be a constant quantity, the two elements power and time are in reciprocal proportion, that is, the one of them increases as the other diminishes, at such a rate as that the product shall remain the same. Thus, for instance, if the whole force is expressible by the number 16, and the power and time are supposed equal, each will be expressed by the number 4; if one of them is multiplied by any number, the other must be divided by the same, as, for instance, if the power, 4, is doubled so as to become 8, the other, the time, must be halved so as to become 2; and so on in all other proportions, their proportion to each other being the greater equal to the less multiplied by the square of the number, which multiplied the one and divided the other in the case of their numerical equality. In consequence of this law of variation, either the power or the time requisite for the performance of any given effect may be imagined to become as small as we please, provided the other increases as much by multiplication as this one diminishes by division. Neither of them can, however, in any imaginable case become nothing, or arithmetically speaking equal to 0, because if one of two factors is 0 the product is 0, whether the other factor be great or small.

The necessary inference from this is, that every action of a material creature, whether it consist in observation by the senses, or in the mechanical exercise of the muscles, must require both exertion and time for its performance. We do not require to state the numerical relation of these to each other, because that varies in every particular case; but we must bear in mind that this is the general principle, and when we apply it to animals we must distinctly understand that both elements enter into every possible animal effort, whether quick or slow, feeble or energetic, and that this holds in the case of all animals, in consequence of the bodies of animals being material, and as such necessarily subject to the law of gravitation, to the exact amount of the quantity of matter concerned in the parts by and upon which the animal action is performed.

Mind, from the very definition of it, is completely absolved from this law of gravitation; and consequently the action of mind, whatever it may be, requires neither effort nor time for its performance. It does not fatigue, and it occupies no measurable duration. In consequence of this, multiplicity of thought (for thought is the general name in common language for the operation of mind) cannot by possibility diminish the capacity of thinking, on any one particular subject, in the same manner as multiplicity of observation by the senses, or of muscular effort in action, diminishes the bodily power in the individual instance. On the contrary, the greater the abundance of the materials or subjects of thought, thinking becomes the more ready. The proper function of the mind, as we feel it in ourselves and judge of it by the conduct of others, is comparison, and an inference drawn from that comparison. The correctness of the comparison, and the truth and applicability of the inference, are the valuable parts of thought; and it is impossible for us to obtain these in such a way as that the comparison may be correct, and the inference useful, unless the grounds of our judgment are complete. Nature, which is the source of all our materials of thinking, as concerns our drawing of inferences, and acting upon them through the instrumentality of the body, is one system, all the parts of

which have an intimate relation to each other; and consequently the foundations of our comparison must fall short of accuracy, in every case, in proportion as we are ignorant of the nature and relations of the whole.

It follows from this, that, as mind is the opposite of matter in definition, the perfection of its exercise must be the opposite of that of the exercise of matter; and that *combination* of thought is as essential to the useful exercise of the mind, as the *division* of labour is to the useful exercise of the body.

This distinction between the most profitable uses of the two parts of the compound nature of man may be said to be the very key of knowledge, and from want of it, or ignorance of the use of it, countless thousands of men in all ages have drudged in thought during the whole period of their lives, in a manner scarcely more profitable than if they had never thought at all.

It is to be regretted that there is a wonderful proneness to this confounding of mind and matter, and making the latter the model or example of the former. We see the advantages of the division of labour by the body, for they are at once palpable to the senses, in the improved products of bodily labour, and the successful conducting of bodily action; and as the effect of a particular mode of conducting thought is not an object of the senses in any meaning of the word, but a result which can be arrived at only by the mind itself, it is not suggested to the mind until the mind has acquired that general knowledge of relations in which it consists. This is the reason why technical men, in matters of thought, are always narrow-minded, and incapable of turning their own technical knowledge to that use to which it might be turned. To use a homely simile, they are in possession of a single bone of the skeleton, loosened from its connexion, and thus are unable to come to any conclusions as to the structure and the functions of that species of animal to which the bone belongs.

To some this may seem irrelevant to the study of the mammalia, but the truth is exactly the reverse; and we have a remarkable instance of it in the case of the late Baron Cuvier. Before the time of that most illustrious of generalising naturalists, there were conjectures about the extinct mammalia, of which single bones are found buried in the soil; and there were classifications of mammalia, better in some instances and worse in others, but all imperfect. Cuvier did not sit down to dote and dream over the fossil bone, and eke out the scanty information which it afforded by foundationless conjectures. He went straight to the living mammalia, dissected them bone by bone, in an immense number of different species; and in every case he took heed of the leading functions which were inseparably connected with every varied form of the skeleton. By patient, skilful, and most truly philosophical labour in this way, he learned to make a single bone an index to the general character of an animal; and by this means he caused the extinct races to stand up before the intelligent mind, clothed with sinews and with flesh, and performing their functions as palpably and as intelligibly to the understanding as if they were now tenanted the earth in the living state.

The result of this was the classification of animals in the "Regne Animal," of which we shall give a brief outline in the sequel; and which, at least in those parts which were moulded by his master hand,

is the greatest treasure that ever was given to the student of nature for sure guidance in his delightful task. There are imperfections in many minor points of this work, because no length of life and no assiduity of labour could put one man in possession of all the facts, and no man can be wise beyond the limits of his actual knowledge. The chain of organisation is also broken in many parts of the animal kingdom, and in none more than in the mammalia; and, as a new means of judgment has to be introduced after each breach, the difficulty is thereby increased, and the sources of error multiplied. In spite of these circumstances, Cuvier has brought the classification of the mammalia, and, what is more valuable, the practical application of that classification, into the light of day; and if he has not done exactly the same with the other three classes of the vertebrated animals, he has delivered even them from the dominion of "Chaos and Old Night." In consequence of the sure foundation which he has thus laid, every succeeding observer of nature and reasoner upon the analogies of nature is enabled to add something to a fabric of science proof against the casualties of time and opinion, instead of, as heretofore, building on the shifting sand, and being at the mercy of every wind of hypothesis and every flood of merely authoritative assertion.

But though this, as being among the last varieties of the organs of most conspicuous external action in animals, is the proper branch of our general subject under which to introduce these few remarks, we must close them, and return to matters of more humble import.

We have said that the digging foot is so similar in its general structure in all the mammalia which have a digging habit, that it is not necessary to go into the details of its modifications, we shall, however, for the sake of those who may be less familiar with the subject, introduce a few figures of the more remarkable of those same digging feet.

The common mole is perhaps the most completely a ground animal of any of the digging race; but a representation of its foot would be superfluous. In order to enable this animal to exercise its fore feet with the requisite degree of vigour, the sternum is more firm than in any other of the mammalia excepting the bats; and it is furnished with a mesial crest as in these, for giving a firm origin to those pectoral muscles, which tear down the earth with a degree of rapidity of which those who have not marked its progress could have but little conception. The head is elongated to a point, in order that it may better pierce its way, and it is furnished with an additional bone in the extremity. The muscles of the neck are also of great power for the size of the animal; and altogether it is remarkably well constructed for the performance of its subterranean labours.

The common mole is decidedly a flesh eater, and though in a state of nature, its principal food consists of earthworms and ground insects and their larvae, it is so voracious and so determined in the gratification of its appetite, that if two hungry moles are confined together, they speedily engage in desperate battle, and do not give it over until one conquers the other, and when this is done, the victor, like a true cannibal, very speedily kills and eats the vanquished, or rather tears open its belly and begins to devour its bowels while it is yet alive.

The next figure of a digging foot which we shall

introduce is that of one of the rodentia family, connected with the rats by the older naturalists, but distinguished from them by very marked characters:

Rat Mole.

It is one of the most singular animals, or rather genera of animals (for there are at least two known species with which we are acquainted)—the rat-mole (*Spalax*). Its head is large, its feet remarkably short, and it has no eyes visible external of the skin, though under it there is a small production of a black colour resembling an extremely minute eye. It lives under ground, and forms a subterranean passage in the same way as the common mole does; but its feeding is different, as it consists chiefly of the roots of vegetables. The blind rat-mole, of which the above is a figure, is rather larger than the common rat; but there is one in Java and the other Isles of the Oriental Archipelago which is as large as a rabbit.

The animal whose digging foot is figured in the above cut belongs to the rodentia, and we shall next introduce one belonging to the edentata, or toothless animals. This is the foot of the Cape animal, vulgarly termed the ground hog. The animal is about

Ground Hog.

the size of a badger, and burrows in the ground with amazing rapidity, all its fore feet being from the structure of the toes remarkably well adapted for burrowing, and also for tearing open ant-hills and other nests of insects upon which the animal feeds. Its nose is very much produced, and its head and ears have some slight resemblance to those of a pig. It is destitute of any efficient teeth, and seizes its insect prey by means of its long and slender protrusile tongue.

The next digging foot which we shall introduce is that of the great ant-eater, an animal which has very great power in its fore paws, the nails of which are curved almost to semicircles, and turned inwards, when the animal walks, in order to protect their sharp points. These feet are not well adapted for ordinary digging; but they can tear an ant-hill to pieces with wonderful

facility, and the animal very speedily transfers them to its mouth by means of its protrusile tongue performing this operation with the greatest rapidity.

The last digging foot which we shall introduce is that of one of the armadillos, which, from its shortness, its strength, and the immense claws with which it is armed, is one of the most efficient of digging

feet. The particulars of these curious animals, and the distinctions of their several species will be found mentioned in the article ARMADILLO, so that we need not repeat them here.

There is one other animal, an extinct one, of the fore foot of which we shall give a figure, because, though the mode of its life is not known, the immense production of some of the bones of the foot indicate that it has perhaps been a digging animal, though it is possible that in reality its manners may have resembled those of the sloths, though what sort of trees could have supported an animal whose skeleton makes that of the elephant itself seem a very slender fabric in comparison, it is impossible for us at the present day to determine. Being an extinct animal, nothing of it is known but the skeleton, which, however, has been found entire in the alluvial deposits of South America, and at a great depth below the surface, which clearly proves that the placing of it there is by no means a recent event. The enormous size, sin-

gular formation, and vastly produced processes of the bones of this animal, together with the fact of its skeleton having been found entire in the fossil state, render it one of the most interesting of the extinct mammalia. It is the *Megatherium* of authors, which simply means, "the great wild beast." The following is a sketch of the foot of this animal.

There is one other digging organ which is worthy of notice, as in the animal which we shall select for illustration, it is not accompanied by feet in any way adapted for burrowing, or even for simply turning up the earth at the surface. There are several of the digging animals, besides the common mole, that use their snouts for assisting them in their operations under ground; and one of these, the star-nosed mole of North America has the snout so peculiarly formed at the extremity, that it is not easy to say what specific purpose it serves in the economy of the animal. The extremity of it is surrounded with a number of cartilaginous points formed like a star, and each capable of considerable motion. The genus, or perhaps rather the family to which we particularly allude, as using only the snout in digging, is the hog family, and the common hog as the typical animal, will serve as our example better than any of the others, because it is very common and easily observed. We need not say that the neck of the hog is remarkably strong for the size of the animal, and that it is furnished with very powerful muscles for moving the jaws; for the bare inspection of the animal will at once convince any one of these facts. The bone of the nose is very long, and the frontal sinuses are large and divided, or ramified into a vast number of cells, so that there is most ample provision made for the development of the membrane containing the olfactory nerves. The rhinoceros is the only animal, the

relative size of whose nasal bone bears any proportion to that of the hog, and though it is much stronger in proportion, it is not so much produced anteriorly. In fact, the enlargement of this bone in the rhinoceros answers a very different purpose from that which it answers in the hog. In the former it seems intended chiefly to support the horn, as it is called, or the two horns in the species which has that number of those appendages. This horn, or these horns, have no core of bone like the horns of oxen and many other ruminating mammalia. They are wholly a production of the skin, and each may be regarded as a great tuft of bristles, somewhat resembling baleen in their texture, but far more firmly soldered together than the fibres of that substance. This horn is a terrible weapon in the rhinoceros, and the bone is made strong in proportion to the action of the appendage. The nasal bone in the hog has no such appendage to support, and therefore it is lengthened, but inferior in breath and in thickness of substance. Its office is to support the snout and its peculiar bone, and this, though very efficient for the purpose to to which the hog applies it, is so far from being fit for a weapon of any kind, that a slight blow upon it pains the animal more than a severe one upon any other part of its body. The snout bone of the hog rests at its under part upon the intermaxillary bones, in front of the sockets which receive the incisive teeth, and at the upper part it is united to the nasal bone by cartilage. Its distal extremity supports the peculiar organ which forms the snout properly so called. This is composed internally of cartilaginous fibres, and its termination, which is nearly circular, is flat, but slopes inwards on the under side. It is naked and full of follicles, which keep the surface moist, and prevent its delicacy from being injured by long exposure to humid earth. The extremity of it forms a kind of elevated ring, and the tissue with which it is enveloped is most abundantly supplied with nerves and blood-vessels. This curious organ is put in motion by two large muscles on each side, the upper one inserted in the boundary of the cavity which receives the canine teeth, and the under one in the lower part of that cavity. These muscles, as well as the muscles which work the jaws are much larger than they are in any animal which has the nose merely as an organ of smell; and their tendons divide into a vast number of fibres, which terminate in the tissue that forms the envelope of the snout. Those fibres take a great many directions, straight, oblique, and spiral, so that the motions which they can communicate to the organ, though limited in range, are very various in direction. The great supply of nerves and blood-vessels point out the sensibility of the organ; for though, as we have said, we are not warranted in concluding that nerves alone, and without the other systems, are or could be organs of sensation, yet it is certain that where there are no nerves there is no direct sensation, and perhaps not much sensibility. The opening of the nostrils terminate in the disc of the snout, and its elongation beyond the nasal bone gives farther scope for the development of the organs of smelling, so that it is highly probable that this sense is most acute in the hog. The sense of smelling is not, however, the proper sense which is allocated in the disc and naked part of the snout; for it is also a very sensitive organ to what is called touch. The elevated ring with which the upper part of the disc of the snout is furnished, and which the animal can elevate

and depress, and move in a great many ways, is the instrument with which it "roots" or turns up the soil. Its action is not unlike that of a plough with a double mould board which turns the furrow both ways, and the projecting ring performs an office something similar to that of the cutting feather of the sock, only it turns up the soil as well as cuts it, without any necessary elevation of the head. It is in quest of the succulent roots of plants that the hog performs this operation, or in the wild state it is in quest of acorns, beech mast, and other forest fruits, which are covered up with fallen leaves, and the mud which is collected or produced by these. When seeking this description of food in places where it is naturally to be found, the hog has comparatively light work; but in moist places where the roots of plants are large and succulent, its labour is more severe. Even in such places, however, it "nozzles" away with great satisfaction, and utters a grunt of apparent delight when it comes to a root more rich or racy than the rest. As the animal is not very handsome in its form, or particularly cleanly in its manners, it is no great favourite with any body, except those who make a profit of it; but still it is an animal whose economy is worth studying, and the structure and action of whose ploughing apparatus are highly curious. It does its work with such apparent ease, that we are not aware of either the complication of structure, or the strength of muscle which it requires, but they are both very great. The following figure affords a slight idea of the external form of this peculiar organ; but its action, and the internal organisation which fit it for this action, are both studies of intricacy as well as instruction to every one who wishes to understand the mechanical action of animals.

There is another short lesson which we may learn from this instrument, and that is the limitation even of the acutest senses of animals to the uses which the animals have for them. There is little doubt that the sense of smelling in the hog is far more acute than the same sense in man; and it is probable also that no single portion of the surface of the human body is so completely endowed with what is called touch, as the naked extremity of this organ. But notwithstanding this sensitiveness in both respects, it does not extend beyond the discriminating and finding of the animal's food, in either of them. The keen-nosed hog is proverbially indifferent to the most offensive odours; and its highly sensitive snout can poke about among substances which we would reckon in the highest degree harsh and grating to the touch. There is no feeling of pleasure or of pain resulting from odour or from touch in the animal; and if he should find food in the one place, and not in the other, "the reek o' the rotten fens" would be far more

gateful to "piggy" than all the "spicy groves" of the fragrant east.

In this, and it is no doubt the same in the case of the senses of all the mammalia, there is a very marked difference from the same sense in man; and this difference alone might, if properly studied, of itself teach us that in man there is something more than the mere animal. We too have our animal sensations, the desires arising from which extend no farther than the supply of our bodily wants. But in addition to these there is something higher, more refined and exquisite, and more enduring. In the case of the animals, when the sense has produced its animal purpose it remains quiescent until that purpose demands a new service: in man, on the other hand, "the eye is never satisfied with seeing or the ear with hearing;" and it is after we have satisfied ourselves with the banquet that we feel the greatest desire for the perfume, and derive the most pleasure from it.

Farther than this, those supplemental pleasures which we derive from our senses, over and above what the animal wants of the body require, are capable of an unlimited degree of cultivation, second only to the general cultivation of the mind in knowledge, and second to that only because they are less general and more immediately allied to the senses. It is impossible to be endowed with the capacity of making a comparison and drawing an inference, without perceiving that there is a trace of immateriality and consequent immortality in this; and any branch of any inquiry is never so profitable as when it leads to a result of this kind, because this result, independently of its own intrinsic value, invariably heightens the usefulness of that from which it arises.

We have gone more fully into the structure and use of digging organs, and the habits of the animals which possess them, than we have done into some others which may at first sight appear to be of more real importance. We have done this for two reasons; first, because the animals which possess them are, on account of other parts of their structures scattered through the system, and there is no work with which we are acquainted, that can afford to a common reader even a glance at them in their juxtaposition; and secondly, because this portion of the mammalia, from the peculiarities of the races which it includes, is calculated to give origin to many trains of thought which, from their unexpectedness, as well as their beauty, are eminently calculated to promote a love of nature and a consequent desire to know it, and at the same time to call forth, in the most pure and lively manner, our admiration of the power, wisdom, and goodness of nature's Author. We regret that our limits do not permit us to enter more largely into those speculations, but as any single one of them is ample subject for a volume, and as we must confine ourselves to a few pages, we must leave them, and pass to another division of our general subject.

Sec. IV.—*Organs of Feeding.*—The grand purpose for which the mammalia, and indeed all animated beings, exist in nature, is that of feeding, and to this all the systems of their organisation, and even the faculty of continuing the race in the several species, are obviously subservient. There is in fact a very strong confirmation of the general position, in fact an absolute demonstration of it in this last circumstance. Each animal is, in a state of nature, perfectly constant to its species—lions produce nothing but lions, bears nothing but bears, and so on through the whole

catalogue. The mules, or mixed breeds, which are produced between some species, in a state of domestication, furnish no objection against this, for they prove only that domestication in so far changes the nature of the animals. We believe that there is no recorded instance of a wild female of any species being the mother of a mule, though there are instances of mules between tame females and wild males. This shows us by the way, that the instinct of preserving the species unbroken is committed chiefly to the female. Those crosses, even when both animals are in a state of complete domestication, and when every art is used to bring them about, in consequence of the superiority of the next progeny over pure blood for certain purposes, can only take place between species which, in all the leading points of their organisation, and all the essential parts of their economy, bear a close resemblance to each other. Even when the mule has been obtained, it cannot maintain itself for even one successive generation. There is not a single instance of the progeny of two perfect mules, that is mules of the first cross, although mules are perfect animals, as well as those of the pure blood of either parent. Their tendency to propagate is much weaker indeed than that of the pure animal of either species, but though weak it does exist, and the male will, in the language of breeders, "breed back to the pure blood," and the more readily the more nearly pure that blood is. We must consider it, therefore, as a general law of the animal economy, that there is in each species a power not only of continuing itself by successive generations, but a power of preserving its species pure and unmixed, which in a state of nature is never broken in upon by contingent circumstances.

The question naturally arises, what is the purpose of this power? What end does it serve in that general system of nature, of which all the parts are so harmonious, that each may be said to be made for the other, as obviously as are the different organs of the same animal? The answer to these questions is easily given. Every distinct species has a distinct part to act in nature's economy, to which part it is, in a state of nature, as strictly confined as the successive generations of each species are confined to that species. This is clearly established by historical testimony and by monumental record. There are countless regions of the world from which, not only since the records of the human race began, but within the period of modern history, races of animals have entirely vanished, though they were once so numerous as to form characteristic features of their several localities.

Within the modern period we cannot regard those extinctions of animals as purely natural occurrences, for man has come in to play his part; and in very many instances, where he did not choose to domesticate he has destroyed, it may be sometimes not with "absolute wisdom." The bones of the animals which speak from the dust give evidence of a more purely natural kind, and therefore more to the purpose. We are not to suppose that the elephant of Siberia was exterminated by human means, or the valley of the Ohio was less wooded or less wild when the mighty volume of the mastodon trode its savannahs. As little are we to suppose that those animals which are found in the earth abundantly in many parts of Europe, and of which the nearest living types are to be found in the tropical parts of the eastern or western continent, were exterminated by human means. Animals slumber

together in one common charnel house, deep under a covering of earth which nature has thrown upon them; and so slumber in Europe; but the living type of the one, or the lingering species of a genus which had once been numerous, is found in South-eastern Asia; that of another is found in Southern Africa, and that of a third in South America. They have not yet been met with we believe, but it is by no means impossible that those ancient sepulchres may contain the bones of the marsupial animals of Australia, widely as they differ from the existing mammalia of every other region on the surface of the globe. Those monumental bones are, in very many of the species, found in no stinted numbers, but in heaps which, ere the mould covered them in the lapse of years, must have cumbered the surface. They have clearly perished by what may be called the hand of nature, that is, they have become extinct in virtue of that law which God has given for the earth's government. That law is a law of infinite wisdom and goodness; and therefore, whether the numbers of an animal have remained stationary, whether they have increased, whether they have diminished, or whether they have become extinct—recently or so remotely that no record of the time remains, we must conclude that all those changes, in every case where they have not been brought about by the interference of man's partial and imperfect knowledge and judgment, have been all for the very best.

If therefore we ask why nature has blotted out, from her living catalogue, such and such a race? the answer is plain and palpable—there remained no longer any place in nature for the exterminated species, it had no useful office to perform for the general benefit of the system, and therefore it was cast away as a vain and unprofitable thing.

We have no room to enter upon the train of inquiry to which this naturally gives rise, as to whether the extinction of so many races of animals is an evidence that our globe is waxing old, and must one day or other, in spite of the powers of local renovation which are contained in it, undergo at some time or other that doom to which its most tiny inhabitant is destined. We have adduced the circumstance merely as a proof, the most exclusively natural which we can have, that every species of animal has its distinct place and office assigned it in the system, from which place and office it can no more of itself depart than the earth or any other planet can of itself break away from the governing influence of the sun, and career as a devious wanderer through the regions of space.

The continuation of the race is, as we have shown, only to keep the necessary office in nature full, and according as the general working of nature maintains steadily, increases, diminishes, or abolishes the office, the numbers of the animal remain stationary, augment, fall off, or finally depart. The only other use, considered with reference to nature, is, as we have hinted, the feeding; that which the animal consumes is a surplus which, if suffered to remain, would injure the rest, destroy the balance, and derange the whole system of nature. This, however, is guarded against in the most effectual manner. In South America for instance, the gigantic megatherium has been laid in the dust, it may be to make room for the ox and the horse, imported from Europe, and now the chief wealth of the inhabitants. In other parts of the world the change has been similar. It is the mighty that are fallen; and it may be that because the feeble

arm of man is unable "to draw out leviathan with a hook, or guide behemoth with a bridle," that those giant creatures have been taken out of his way, in order that he might clothe the hills with flocks, people the meadows with herds, turn the furrow by the labour of the all tractable horse, and thus subdue the earth and reign over it, according to the gracious promise made to him at his creation. This is a part of the study of the mammalia which is truly inviting, but we dare not enter further upon it, lest it should tempt us beyond the bounds even of rational speculation.

The animal is not only useful in removing that superfluous substance, animal or vegetable, which it appropriates as its food, for the refuse of that food, the portion of it which is unfit for assimilation by the animal, together with the remains of the animal itself after it has performed its appointed work, and rendered up its life, are most useful in promoting the growth of the vegetable tribes, which in their turn supply the food of by far the greater number of land animals, whether mammalia or any other class. There is thus in the system a perfect cycle of reciprocity by one supporting another, that other a third, the third a fourth, and so on till, at the end of a succession which we do not see, the last supports the first; and thus the system of terrestrial nature has all the stability and returning into itself which we find in the orbit of a celestial body, at the same time that it admits of a countless number of motions and changes.

We must not, however, endeavour to trace this cycle in any one of the kingdoms of nature taken alone; for, if we do, error must be the inevitable consequence. There neither is, nor can there be, a complete chain or circle of succession in any one of the kingdoms, into which, for convenience of study, we arrange the productions of nature. The chain to which we allude is not confined to the mammalia, or to animated nature taken in its utmost latitude. It extends to the earth, the air, and the sea, in all their successive phenomena, whether momentary, diurnal, annual, or for longer periods of time; it extends to the sun, whose influence furnishes the grand stimulus to the whole system of sublunary things; it even extends, though by fainter shades—shades not traceable by us, to the whole solar system; and by shades fainter still, from that system to the whole material universe, the conception of which is infinitude to the human mind.

Thus, it has always happened, that when a zoologist, a botanist, or any other labourer in one detached portion of the great field of nature, has attempted to trace a regular succession in the productions of that portion, from the most simple to the most complicated, it has invariably been a failure, and wherever there has been candour enough to own it, the breaks in the pretended chain have been more numerous than the continuities. The balance and perfection are in the whole; and in order to preserve these, one department must necessarily be frequently breaking in upon another, and the grand innovator time changing the whole, by degrees too slow no doubt for our perceiving them by immediate observation, but still not the less certain upon that account. A very little reflection may suffice to convince any one that it cannot be otherwise. The whole, however extensive it may be, must partake of the general characters of the parts of which it is made up. Now there is no individual production of nature which is not in a state o

constant change. The progress of this change, so as to be perceivable by us, may require a longer or a shorter time, a moment for instance, for the appearance and reappearance of the lightning's flash, and millions of years (we know not how many) before a world or a system of worlds shall require to be renovated. But still it is sound philosophy to conclude that as are the parts so must be the whole, and the difference is a question only as to time.

Some such general views as these are necessary to put us on our guard, when we endeavour to examine the natural uses of the productions of nature; and when we attempt to define one production as the need and another as the user, we bring ourselves under the lash of the philosophic satirist:—

Prood man exclaims, "see all things for my use!"
 "See man for mine," exclaims a pampered goose!

With the understanding that the great use of the animal to nature is its feeding, and the reciprocal use of nature to the animal is the food and the other means of life which the animal affords, we may proceed to take a brief glance at the feeding organs in the mammalia. Those organs may be conveniently divided into three sections:—Organs of prehension, that is, organs for bringing the food within the possession of the animal after that animal has, by means of its organs of locomotion, arrived at the place where the food exists. Organs of preparation, or those by means of which the animal dresses the food so as to be fit for the ultimate process of being changed into the substance of the animal. Organs of assimilation, including the stomach and intestinal canal, and also the various apparatus through which the chyle or prepared food passes, before it mingles with the blood of the animal. The succession here might indeed be carried much further than the three steps which have been enumerated; for we might at least attempt to ascertain by what organisation and what process the food of the animal, which enters the blood apparently as one simple substance, is changed into each of those numerous textures of which the body of the animal is made up. Here, however, we fall upon a difficulty the solution of which is beyond the reach of the human powers; for these operations have no apparatus other than the organ which is formed; and therefore each of them involves the question of the principle of life, a principle of which, in any thing but its mere phenomena, we must remain for ever ignorant.

Organs of Prehension.—Of some of these we have already spoken, when noticing the other functions which they perform, and which in many instances are their predominating, or more essential and appropriate functions—as for instance, the paw of the ape, though the animal may seize its food with it, is yet more useful to it in a state of nature, in climbing to the place where that food is obtained. Those which we have noticed under their prehensile function, as simply taking hold, we shall not again repeat; and thus the subjects of our present remarks will be reduced within a much narrower compass. They will fall under the following heads: prehensile noses, prehensile lips, prehensile teeth, and prehensile feet; it being understood, in the case of the last, that the foot is used exclusively in seizing the food.

A prehensile nose, or proboscis, as it is termed, is a rare organ among the mammalia; the only instance in which it decidedly appears being that of the ele-

phant. In both the Asiatic and African species of that splendid animal, the proboscis is, however, one of the most important organs of the whole range of the mammalia; and it may with truth be said, that while no organ is more perfect in its structure, there is none for which the possessor is so totally without a substitute. In this, of course, we allude to external organs, for if any of the internal organs of an animal is entirely destroyed or removed, that animal must perish as a matter of course. Among the other mammalia we scarcely know of any external organ for which there is not some substitute, so that, however severe may be the privation, and however great the inconvenience, which the animal suffers from the want of it, still it is not utterly wretched, the functions of life can still be carried on, and various actions can be performed by the other parts of the animal, the performance of which, in ordinary cases, devolves entirely upon the one which in the case of the mutilated animal is wanting.

We have remarkable instances of this in the human subject. There are many instances recorded of persons who, being entirely deprived of sight from their infancy or from a very early period of life, yet acquired so much acuteness and tact in the remaining organs of sense, that they not only performed many operations which are usually supposed to depend entirely upon sight, but actually excelled in the performance of them.

The proboscis of the elephant is perhaps the most extraordinary instrument in the whole range of the animal kingdom, and we could not name another which is of such essential and indispensable use to its owner. Deprived of this the elephant would be utterly helpless, incapable of either eating or drinking, and therefore unable to live. Why the largest of the land mammalia should be thus exclusively thrown upon a single instrument for the supply of all its wants, craving in proportion to its size, is a singular question in physiology, but it is one which we are quite unable to solve. From the fact, however, of there having been, in former times, an elephant in the polar countries, from the probability that the megatherium may have been a proboscised animal, and from the fact that the native grounds of the existing elephants both of Asia and Africa, have been narrowed within the period of recorded history, we must conclude that the elephant, in its proper nature belonged to a state of things which is now passed or passing away; and that in the forests near Chittagong, and by the streams of Southern Africa, the elephant stands monumental, to tell the tale of a state of things of which we have hardly any other living record. These are matters, however, into which, though fancy tempts us on, philosophy is unable to follow; and therefore we must let them remain in the class of what must be admired but cannot be understood.

Still, even within the limits which our examination can reach, and where fact and fancy go hand in hand, the proboscis or trunk of the elephant is a most extraordinary piece of animal mechanism. Hands, clutching paws, feet for holding on, prehensile tails, and all other working structures of animals with which we are acquainted, follow one general law. The basis of these consists of bones, and those bones give origin and insertion to the different muscles by which the action of the parts is produced. But the trunk of the elephant sets this—which we would be apt to

consider as the fundamental law of animal mechanics—at perfect defiance. It contains no bone upon which a muscle can be inserted; and yet it is capable of more varied motion than any other organ in the whole range of the animal kingdom. Nor need we wonder that the animal should take the utmost care to protect this instrument from those predatory animals by which it is occasionally assailed, because injury to this would be far more fatal to it than injury to any other part. Hence we find that when the elephant is compelled to submit to the spring of the tiger, it preserves its trunk with the utmost solicitude, and if it cannot receive the enemy upon the tusks, which are its natural defences, and placed in the same plane with the trunk, one on each side, as if they were expressly intended for defending that, it receives him upon some part of its body, where it can instantly lounge down and crush him under the ponderous weight of its body.

The trunk consists of a double tube or canal, being a continuation of the nostrils, lined with a fibro-tendinous membrane, the perfect flexibility of which is secured by a number of follicles which open on the surface, and constantly discharge a lubricating fluid. The canals of the trunk do not pass directly to the lungs of the animal, but have various flexures; and at the proximal extremity of the organ there are placed tendinous valves by means of which the passage to the lungs can be opened or shut at pleasure. Externally, the covering of the trunk, especially at its distal extremity, is a very keen organ of touch; and the termination, which consists of a prehensile lip and a finger-like projection, can pick up the smallest substance with all the neatness of a hand, while the organ altogether can perform many offices which no hand could possibly perform.

The interval between the two tubular openings of the trunk, and also the walls which surround them, are made up of fasciculi of muscular fibres, which, though they appear, generally speaking, to stretch longitudinally, are capable of moving in all directions. There are, generally speaking, four principal muscles in the organ, which are inserted, the two large ones on the frontal bone and the upper part of the bone of the nose, and the two others on the maxillary bone before and under the eyes. None of the other animals, which have a motion of the nose, have any thing like such powerful or produced insertion upon the bones, as is possessed by the elephant; and it is this firm basis which gives support to the very extraordinary motions of the trunk. The tapir makes a slight approximation in this respect, but even it is nothing to the elephant, which must thus be considered as standing alone among living animals, and pointing at habits and at a locality which are as peculiar as the animal itself.

Each of these pairs of muscles is composed of two kinds of fibres, the one placed longitudinally, and the other radiating in a transverse direction. These are so inserted in the external membrane of the trunk, and in the membrane which lines its two cavities internally, that, though they give it every sort of motion in extension, in contraction, and in flexure, they do not diminish the size of the internal openings, which remain the same in all the variety of its motions. Internally it may be considered both as a drinking horn and as a watering machine. It takes in a considerable quantity of water, pure if for the drink of the animal, but mixed with mud if for the purpose of

riding it of flies and other insects which annoy the skin. In taking up water of either description, it is drawn by suction as far as the valves at the base of the trunk; but these are closed the instant that the water reaches them, and thus not a drop can pass from the trunk into the lungs of the animal. When the water is for the purpose of drinking, the head is elevated, the trunk recurved till the extremity of it enters the mouth; and then an expiration of the air from the lungs opens the valves and discharges the water with no inconsiderable force. If, on the other hand, the object is merely to cool and refresh the skin, successive trunkfuls of water are projected over it with no inconsiderable force, and with as much certainty as if they were projected by a garden engine; so that, by means of this instrument, the elephant can remove annoyances from its skin with more ease and certainty than can be done by any animal which has merely the use of its mouth and paws.

The localities which elephants inhabit in a state of nature require such a provision as this. They are the most fertile parts of tropical countries, rank with tall vegetation, abounding in moisture, and by necessary consequence infested with insects. When we see an elephant which has been for some time exposed to the dry and cold air of our climates, its skin appears wrinkled and shrivelled, and we are apt to imagine that it is entirely destitute of feeling. This, however, is quite a mistake; and it appears to be a very general law in the character of the mammalia, that the sensibility of skin is in proportion to its thickness. This holds in the human subject as well as in every other; for we find that the skin of the palms of the hands and the soles of the feet, which is, generally speaking, the most sentient in the body, becomes, when indurated with tannin, as thick as the hide of a buffalo. There is another circumstance which shows the great sensibility of the skin of the elephant, and that is the singular power of the sub-cutaneous muscles. The action of those muscles, without the stirring of a single limb of the animal, or even without any specific motion of the body, is quite sufficient not only to rid it of any common incumbrance, but to shake off a beast of prey when clutching with its feet and grasping with its teeth. This is the ordinary way in which the elephant gets rid of any animal which attacks it; and the moment the attacker is thrown off by this singular movement of the skin, the elephant is ready to fall upon him or trample him to death.

It is in the finding of its food, however, that the efficiency of the elephant's trunk most remarkably displays itself, and displays the function not only of one hand, but absolutely of a pair of hands. While one part of it coils round a branch and brings it down, the other part lays hold of the leaves on the extremity, pulls them off, and conveys them to the mouth; and thus the elephant can feed upon vegetable matters higher above the ground than any other animal. Nor is the efficiency of this curious instrument confined to such operations as those; for in the arid season, when the ground vegetation is burnt up, and all that remains on the surface is a few withered stalks of grass, almost as hard as wire, the trunk can be applied in collecting them with a neatness which no hand can accomplish. It sweeps like a broom by its lateral motion, and coils as lithely as a serpent; and when it has swept the dried grass in sufficient quantity, it can form it into a little bundle and convey it to the

mouth, in a manner to which there is no parallel in the rest of animated nature; and thus independently of its supposed sagacity, the accounts of which have been often greatly exaggerated, the elephant is, in respect of mechanical structure, among the most wonderful of all the mammalia.

The foot, clumsy as it appears, comes wonderfully in aid of the trunk in some of the nicer operations. This foot can in no respect be compared to a hand, for the toes are completely enveloped within the thick skin of the member; and to external appearance there is no organ in the whole animal kingdom more clumsy and ungainly than the foot of the elephant. We must not, however, judge from mere external appearances when we wish to ascertain what an animal can perform; for this foot of the elephant, clumsy as it seems to be, and incapable as it is of performing the ordinary operation of grasping, is notwithstanding a very ready instrument. The animal can press down a branch with it, or hold on a tuft of grass to prevent its being drawn out of the ground, while the trunk twists off the eatable part as neatly as if it were cut off with a pair of scissors. In tame elephants which have been taught to uncork a bottle of water and swallow the contents, we have a beautiful instance of the manner in which the foot and the trunk work to each other. The bottle is taken by the trunk in a coil near the extremity of that organ, and carefully conveyed under the side of the foot, where it is invariably placed in a direction nearly perpendicular and with the cork uppermost. The lip and finger of the trunk are then applied to it; and however small the portion of cork above the neck of the bottle is, they seize it so tightly that by the twisting motion of the oblique muscles they twirl it out almost exactly in the same manner as would be done by a cork-screw. After the cork is extracted, the animal brings the bottle to an upright position, and coiling the trunk round it conveys it to the mouth without spilling a single drop. The mode in which this is done is well worthy of attention, as showing how very wonderful an instrument the trunk is, and how much superior it is even to the human hand in the universality of its motions. Generally speaking, the most powerful curvature of the trunk is downwards, as that seems to be the mode of its action in taking the food of the animal when in a state of nature. With the water bottle, however, it can have a lateral motion, and so balance the bottle as that not a drop is spilt until the mouth is reached, though when that is arrived at, the bottle is inverted in the neatest manner. It is not easy to explain, or even to understand the singular mode of the coiling of this curious instrument. It does not lay hold by a single part, and so convey food to the mouth as is done by the hands or paws of those animals which use these instruments in feeding; for the elephant can advance the coil on the trunk, and keeping firm hold of a bundle of grass or any other substance which it wishes to convey to the mouth, it can roll it upwards in the coil, while the lip and finger of the trunk are kept ready for seizing some new object.

It would be utterly impossible for any organ composed of jointed bones to perform any thing like the number of motions of which the trunk of the elephant is capable. Generally speaking, all articulated organs have one principal plane of motion, and out of this plane they move feebly and unstably. The only way indeed that free motion of bones in all directions

can be produced is by ball and socket joints, and these joints never can have a steady motion in any one direction, unless that in which antagonist muscles of nearly equal power are applied to them. There cannot be many pairs of such muscles applied to any one joint, and this is the reason why, in the knee and elbow joints, the oblique or rolling motions are effected by the application of a second bone, the action of which turns the joint round upon the centre of the principal one. The spines of the cartilaginous fishes make a slight approach to the trunk of the elephant, but even in them it is only a slight one, for the bone though flexible, is still much stiffer than cartilage, and besides it has the disadvantage of being internal or central of the muscles which move it, and thus those muscles have to act at the greatest disadvantage. The trunk of the elephant, on the other hand, has a structure resembling that of the invertebrated animals in which the muscles are inserted on the skin or crust, and thus act directly and to their full extent, without any loss of power.

It is not a little singular that, in the largest and we may add the rarest of the mammalia, and one which possesses so much intelligence and resource as are found in the elephant, we should, in its most important organ, have a complete departure from the ordinary mode of organisation among mammalia, and the part be as it were, thrown among what we are accustomed to consider inferior classes of animals. The mollusca and the annelidæ are the animals which in their structure come nearest to the trunk of the elephant; and when we examine the extensions and contractions and the various flexures of a worm or a leech, or of a slug, which are all produced by internal muscular effort without the assistance of any bones, we have before us no bad type of the action of the elephant's trunk. It is well known that a common earth worm can bore its way by muscular exertion alone, where the strength of none of the mammalia could enable them to follow it; and it is equally well known that no aperture is too small or too sinuous for preventing the passage of some of the leeches, especially of those ground-leeches which inhabit the eastern Archipelago in myriads, and are such torments to the inhabitants during the rainy season by crawling up their legs and sucking their blood at every pore. But these are motions of the whole animal, and not the working of a part; and even in their particular motions they are excelled by the trunk of the elephant. In their muscular action, whether it consists in extension, in contraction, or in flexure, the muscle passes fairly from side to side, through the centre of the body. The two tubes by which the trunk of the elephant is perforated, give it an advantage over all animals, or parts of animals which have the muscles extending the whole way from side to side. The internal sheath of the tubes, and the external covering of the organ, afford (as there are two tubes), nearly three times as much insertion for muscular fibres as there is in an animal which has its muscles extending from the covering on the one side to the covering on the other; and while both the external and internal coverings of the trunk are endowed with a very high degree of sensibility, both of them are joint all over, and one cannot help feeling admiration at the few words in which the inimitable Bard so perfectly characterises the elephant when he simply says, that it

"Twines its lithe proboscis."

It is true that the most powerful action of the

elephant's trunk is in the mesial plane of the animal's body; and that, as is the case with all actions of the body and head of mammalia, it is most energetic in the downward direction, or in drawing substances towards the mouth of the animal. Still, however, it is capable of motion in many directions, and those varied motions increase towards its distal extremity, so that that part of it can turn like a serpent.

The muscles by which these motions are brought about have their origin in the individual fibres, in the cartilaginous lining of the nasal tubes, and they have their insertion in the skin of the organ, which is also firm and cartilaginous, in order to allow them a proper base for support. This transverse position of the fibres in these muscles is absolutely united with the longitudinal one, extending all the way to the bones of the face, upon which the bases of the great muscles are inserted. This produces a double muscular action, of which we have hardly another example in the whole organisation of the mammalia. The oblique fibres draw the two integuments together with a twisting motion, and the longitudinal fibres being united to them by cartilage, pull them in a proximal direction, much in the same manner as the hand pulls the string in drawing a bow. It is not easy to estimate numerically the force which those muscles possess; but we may state generally that it is more than double of what could be exerted by the same mass of fibres, if those fibres were all exerted in planes parallel to each other, and their action were confined to that simple shortening which is the operation of ordinary muscles. It is sufficient to mention that, when the longitudinal fibre draws the oblique one, then comes into operation that mechanical power with which sailors are so well acquainted, which is technically known by the name of the swig or rope power, and consists in pulling down the middle or bight of a rope, by which means it may be rigged far more tightly than it could be by any mechanical power, however great, applied simply at one end. The great strain of the rope in swigging is upon the two extremities to which it is fixed; but there is a peculiar combination of leverage and elasticity propagated along both ends from the bight; and this telling upon the oblique fibres in the trunk of the elephant, and pulling the external and internal integuments closer together, produces an absolute lengthening of the member, although the longitudinal fibres acting alone would tend to shorten it.

In these muscles, indeed, there is a very wonderful combination of general and individual power, so that while the whole trunk acts in a particular manner, the individual parts of it have their specific actions at the same time, and it twines about with even more flexibility than a serpent, at the same time that its strength and quantity of substance increase so beautifully from the extremity to the insertion on the bones of the face, that it is really more stable in all its varied motions than any organ which could possibly be formed of internal jointed bones with muscles applied to them. Nor is this the most extraordinary part of the structure, curious though it is, for the trunk is absolutely stronger than if it were composed of one entire solid. Every one in the east acquainted with mechanics must be perfectly aware that, within certain limits, a hollow tube is much stronger than a solid of the same quantity of matter. This arises from the resistance of four surfaces to a cross strain; and as the resistance in the case of a tube is merely a

dead or passive resistance, while the resistance of the elephant's trunk is an animal or active one, there is in the trunk a very great advantage over every thing which can result from anything connected with inani-

Trunk of African Elephant.

mate matter. We must, however, take leave of this extraordinary organ, and as no illustration can convey an adequate idea of its action, it being impossible to represent motion by a drawing, we shall content ourselves with giving two simple cuts, one representing the trunk of the Asiatic elephant and the other that of the African.

Trunk of Asiatic Elephant.

We may however remark, in passing, that the trunk is supplied with two distinct kinds of nerves; that the one set are branches of the facial nerves, and may be regarded as more immediately concerned in what may be considered the vital or involuntary

actions of the trunk, while the others are branches of the fifth pair, or nerves which supply the organs of sensation.

The next organs of prehension, or seizing the food, to which we shall allude, are the soft parts of the mouth, of which we need not add that the chief are the lips and tongue. In carnivorous animals, and, generally speaking, in animals which seize their prey with teeth, there is very little motion in the soft parts of the mouth; and in some the most powerful action of the lips is that which draws them away from the teeth, in order to expose these more completely to the work which they have to perform, of which we have a familiar instance in the snarling of a dog. In grazing animals, on the other hand, both lips and tongue are always more or less prehensile. In those pachydermatous animals, which do not root up the earth like the hog tribe, there is always a good deal of prehensile motion in the lips, especially the upper one. The rhinoceros, the tapir, and even the hippopotamus afford examples of this prehensile lip, more or less conspicuous in the different genera, but in no case amounting to an independent prehensile instrument like the trunk of the elephant; the most efficient of them are merely auxiliary to the mouth in gathering in the vegetable matter which is cut from the surface of the ground by means of the teeth, or in bringing more elevated vegetation downward, so that these instruments can divide it. There is less of this action of the lip in the rhinoceros than in any other animal of the order; and the rhinoceros requires it less, inasmuch as its chief food is torn by the very powerful teeth with which the jaws of the animal are furnished.

The ruminant animals have also some prehensile action in the lip, and they have more in the tongue than any of the pachydermata. Perhaps the most remarkable instance is that of the giraffe, which, while it has the lips capable of seizing and conveying into the mouth the leaves, twigs, and other vegetable substances upon which it feeds, has the tongue a directly prehensile instrument, with which it can seize a branch of a tree and bring it down till the leaves are within reach of the lips.

There are some adaptations to locality in these parts of animals which are not unworthy of attention; and they are the more worthy of this attention, inasmuch as the larger mammalia, which feed upon vegetable matter, are the grand indexes to the vegetation of a country, and through that to its general physical character, as respects its value for human cultivation or the reverse. One of the most valuable of these indications is, that the country furnishes a supply of food for these larger herbivorous mammalia, which are the most profitable, on account of their milk, their labour, and the value of all the parts of their structure; and also from the great return which such animals make to the soil on which they feed. Hogs mangle the surface, and the rodent animals, even when they do not burrow, spoil the vegetation. It is therefore of use to attend to the modes of feeding. If the animal subsists chiefly by browsing the short herbage of upland downs, and other places of a similar description, there is little prehensile motion either in the lips or the tongue; and the sheep and goat may be regarded as examples of this kind. If again the animal grazes the taller vegetation of meadows and other fertile places, the tongue has more prehensile action, and it sweeps

round to gather the herbage as it is divided by the teeth. The whole of the ox tribe furnish examples of this mode of action. If again the animal has, either habitually or seasonally, to gather the dried grass from the surface of the ground, the lips have more prehensile motion, as we find exemplified in the horse and the ass. Yet again, if the animal is habitually or seasonally reduced to browse trees, in consequence of the disappearance of surface vegetation from its pasture, it has the lips and also the tongue still more prehensile, as we find exemplified in the camel, and still more decidedly in the giraffe.

There is not only this gradual adaptation in these grazing animals to the peculiar nature of their different localities; but the whole organisation of the animal corresponds with this. The lengthened neck and comparatively small head of the camel and the giraffe, and also the free motion of their fore legs, and the extent to which they can stretch these from each other when circumstances render it necessary, all tend to enable the animals more conveniently to find their food, whether they are obliged to seek for it above or below the ordinary plane of the body.

We shall now take leave of those parts of the head of the mammalia which, with the exception of the teeth, are the principal organs of that part of the body used in seizing food. There are no doubt various other animals which have the tongue extensible a considerable way beyond the ribs, and capable of some prehensile action. This is the case with the bear, which is in the habit of reaching the sweet juices of vegetables in the tubes which contain them, after the animal has divided a portion with its teeth, in order to procure their admission, and which also by the same means get at honey in the holes of old trees, which they are incapable of reaching directly with the mouth. The ant-eaters have also this faculty to a considerable extent; but as their object is not to lick up substances with the tongue, but to possess themselves of insects and their larvæ, their tongues are furnished with a viscid secretion to which the insects adhere, as they do to a similar substance on the tongues of birds and reptiles which, like the mammalia in question, feed upon insects.

There is another portion of the organisation of the ant-eater, which aids the prehensile tongue in the capture of the animal's insect-food; and without this the power of the tongue could not be effectually called into operation. That to which we allude is the fore-paw of the animal; and, in order that it may be better understood, we have given a bird's-eye view of the anterior part of the animal, together with the skeleton of the fore paw, which will be found at page 163.

It will be borne in mind that this animal is entirely toothless, incapable of biting, or of offering any violence to an animal so large as a mouse; yet one of the species at least is an animal of considerable size, being more than four feet long in the body, and two feet and a half in the tail; but it is a very slow and inefficient walker. From its large size, it must require a considerable quantity of food; and as that food consists of very small insects, the finding of it must be attended with no inconsiderable degree of labour. Now, whatever may be the kind or quantity of food necessary for any animal, the organisation of the animal is in every case the best adapted for finding that food in all the three parts, of getting at the

situation where it is, taking possession of it, and turning it into nourishment. Hence if we find that the locomotive powers of the animal are slow and imperfect, we invariably discover some other more fully developed part of its organisation, which compensates for its deficiency in this respect. The ant-eaters form no exception to this. They are deficient in locomotive power, and they are destitute of teeth; but we find an ample compensation in the peculiar form and enlarged processes of the bones of the fore-paw. The scapular bone has prominent ridges upon it which give it a firm embedment among the muscles; the articulation of the head of the humerus is very free; and there is hardly another of the mammalia in which the processes on this bone are so well adapted for the insertion of powerful muscles. The elbow joint has also great power, and the projecting head of the ulna affords a lever from which a very extraordinary twisting motion can be given. The position in which the head of the animal is shown may be regarded as that of repose, or of the slow motion of the animal. In this state the powerful claws are folded down partially on the sole of the paw, and seem quite helpless, and indeed useless for any ordinary species of motion. If indeed we were to estimate this animal as the standard of walking animals which have to range over a great extent of surface for subsistence, we should feel disposed to assign to it that degree of deformity and imperfection which some authors have assigned to the sloths. When, however, we take the nature of its locality into consideration, as well as its structure, we find that no animal is more completely fitted for its place in nature. Indeed if we take the trouble of observing how strong and well made out in all their parts the bones of the fore-arm are, it is impossible for us to suppose that such a perfect instrument could have been formed without an adequate purpose. One of the toes, the middle one, and also the claw upon it, is much larger than the others, which can be regarded as little else than lateral supports to this most powerful one; and in some of the species, or at least in animals of analogous habits, the number is reduced to three, or even to two. This, however, allows of no inference against the strength of the organ; for nature, like an engineer of the most consummate skill, concentrates her work upon a single part, when she is to work to the utmost of her strength.

The lateral toes on each side are, as will be seen, gradually shorter the one than the other, so that they form excellent supports; and the carpal bones are almost as perfect as those of man himself. We cannot call this instrument a hand, because it is not adapted either for grasping with the fingers or for clutching with the claws; but notwithstanding this it is not only a hand for the purposes of the animal, but a hand ready armed with a tool by nature herself.

When the animal reaches an ant-hill, or the colony of any of those analogous insects upon which it feeds, the paw is extended, and the toes and claws bent, so that it advances like a hook; and as, from the shortness of its legs and the length of its body, the animal has a remarkably firm base upon the ground, the hook of the paw is drawn through the substance of the ant-hill with much more force than a man could draw a hoe with a single prong. The twisting motion of the elbow joint comes also into play; and altogether the breach which a single stroke makes in the ant hill is much greater in proportion than that

which an ordinary breaching battery could produce in a fort in the course of a day. The insects upon which the ant-eater feeds build their habitations with no small degree of labour; and they are seldom backward in defending them from aggression, or in making repairs where injury has been done. From this disposition of theirs, they throng to the breach made by the ant-eater in myriads; and the animal is enabled to transfer them to its mouth in great numbers, and with a rapidity which is hardly equalled in the feeding of any other animal.

Claws used for such a purpose as this require to have keen points, because the places which they attack are often very much indurated in the surface. The length of claw necessary to perform the operation of the animal properly, and also the position which it has to assume in the performance of it, are both incompatible with a retractile claw like those of the cat family; and yet the point has to be protected from the injury to which it would be liable if its point came to the ground in walking. Not only this, but the claw is not in any animal a proper base to start from in walking; and accordingly those clawed animals, which are the most decidedly digitigrade, always spring and also receive themselves upon the pads on the under parts of the feet, and never upon the claws, or directly upon the bones to which the claws are immediately attached. Whenever an animal springs from a hard point of rest, covering the extremity of the foot, that point of rest is invariably a hoof embracing the terminal bone or bones all round, and never a claw.

The flattened claws of the more characteristic burrowing animals, which are necessarily worn in the operation of digging, form no exception to this; for if the animal has the claws of moderate length and is digitigrade, the walking is performed on pads; and when the claws are very long, the foot is plantigrade. The length of claws, and the free motions of the bones of the paw which are required in the case of the ant-eater, are not compatible with even an ordinary plantigrade motion; and therefore the position of these animals when only the leg is brought into action, and not the paw, for its peculiar purpose, the foot is turned on the side as represented in the sketch above given. These ant-eaters are very peculiar animals, but they are not more peculiar than the localities which they naturally inhabit. These are the close and marshy forests of South America, in which insects swarm by myriads, and where, were it not for such animals as these, the insects would speedily get the better of every other tribe of animals, and the forest would be changed to a desert. They are necessary in these seasons, because the substance which they consume would be equally destructive if allowed to accumulate beyond a certain extent; but the law of nature controuls both, and sets regulations over them which adapt with the greatest nicety their numbers to the necessity there is for them.

There are in the American continent the remains of a race of animals of far more ample dimensions than the ant-eaters, but still bearing some resemblance to them in the structure of the feet. We have already introduced a sketch of the foot of the megatherium, the most gigantic of these animals of which we have any acquaintance; but, to save reference, we repeat it from a different specimen.

It will at once be seen that, though we have no personal knowledge of the habits of the owner of this

foot, they must have been very different from those of the ant-eater, though there is too much production

of the bones of the toes for allowing us to suppose that the foot had not some other function than simply that of walking. The foot is indeed well made out both in the form and the number of its bones; and when clothed with the soft parts and their integuments, it must have formed a very good support upon soft surfaces, even to a very ponderous animal. The great strength of the bones is, as will be seen, towards the extremities; and the claws must have been of moderate dimensions, so that the animal could walk on the entire flat of the foot; and to enable it to do this the better, there is some approximation to a heel bone, though it is very imperfect as compared with that of the human foot. It is a portion of the fore foot which we have represented; but the hind one does not differ materially, except in having the toes turned outward, which position would have been calculated to give still greater stability to the animal. We cannot of course speak positively as to the use of this foot, or guess at the economy of the animal, farther than it has obviously been a vegetable feeder; and though it has sometimes been supposed that the feet have been used in digging the roots of vegetables from the marshes, we can have no certainty upon this point; neither do we know whether the animal was or was not possessed of a prehensile proboscis. The teeth are flat on the crowns, like the cheek teeth of the elephant, which are the only teeth that it can use in the grinding of its food; but the row is continued quite round the front in both jaws, and thus the animal would have been capable of dividing vegetable matter, which, from the great size of the bones of its head and their numerous processes for the insertion of muscles, there is little doubt, with a force unknown among the living mammalia.

The megalonyx, the remains of which have been met with in North America, though never in such perfection as those of the last mentioned animal have been in South America, lead to the supposition that, if really different animals, they must have been similar in their habits, though we of course are not better acquainted with the habits of the one than with those of the other. None of them belong to that period or condition of the world which comes within the scope of our authenticated history; and therefore it is probable we must for ever remain ignorant both of them and of the changes of the countries which they once inhabited, which have been taking place during the lapse of probably very many centuries. We know enough of these animals,

however, for enabling us to conclude with perfect certainty that they have been both, strictly speaking, vegetable feeders, slow and unwieldy in their motions, and neither disposed to offer injury to any other animal, nor capable of doing so, unless in defending themselves against enemies, with the means of which vegetable feeders are provided very nearly in the proportion of their size.

Among the feet of animals which assist, partially at least, in the taking of their food, we ought to have given some slight additional account of the foot of the elephant. Its foot is well made out in the bones, although the parts are much concealed by the thick and loose skin by which it is enveloped; and the animal can readily turn it to account, both in holding on upon the ground, in the use of the trunk, and bending branches till they can be reached by that very singular organ. The foot of the elephant is not, however, a prehensile foot in any of the ordinary senses of the word, inasmuch as the animal can neither seize any portion of its food with it, nor convey any substance to its mouth. It is a very firm organ of support, but this is its proper function.

The feet of the extinct animals of America bear some resemblance to the foot of the elephant, but not much. In the elephant's foot the last phalanges of the toes are but little produced, while in the American animals they greatly exceed all the others, and are the portion upon which the great strength of the foot appears to be concentrated, while in the elephant the concentration is on the centre of the foot, and the bones of the ankle stand nearly perpendicular the one over the other.

We shall now offer some short remarks, and give one or two illustrations of prehensile feet of a very different character, form, and use, from those to which we have hitherto alluded; we mean those feet which are adapted for the capture and for the rending of living prey. The cat tribe are the characteristic animals of this description, though there are some which perform the same action in a slighter degree.

The leg and claw of the Lion.

We shall therefore confine our observations to them, and chiefly to the lion, as at once the most powerful and the most typical of the whole. In the preceding

eat we have given a representation, both of the form of the muscles in the leg of the lion, which perform the grand or general movements of that organ, and also of the particular formation of the toe of the lion, in consequence of which the claw when not in use is so perfectly protected from injury, and yet enabled to act so readily and so powerfully when the wants of the animal require it.

The one of these figures represents, as well as it can be done in a small sketch, the various muscles, together with their tendons and ligaments, which work the claws of the lion's fore paw; and this paw, although the hind one is also powerful, is by far the most efficient in the economy of the animal.

Upon examining that portion of the cut which represents the full length of the claws (though the integuments are in great part dissected away), and the wrist and greater part of the fore arm, it will be seen that in the form and arrangement of the muscles there is no inconsiderable resemblance to the human arm. We might have been prepared to expect this from the analogy; because, though the paw of the lion is not only a better walking instrument than the human hand, but is really a very efficient instrument for this purpose, yet walking is far from being its only or even its chief operation. The paw of the lion no doubt conveys him to the place where his prey is to be met with, and he runs moderately fast, and struts and stalks on his slow march with all the majesty of a Hercules; but notwithstanding this, the muscles on the fore arm of the lion do not take a leading part, or even very powerfully assist in the walking motion. Their purpose is the working of the paw, the extensors on the upper part and the flexors on the under, just as in the human arm. Those great muscles, as will be seen in the figure, have all their tendons bound round with a very firm ligament, which forms a separate pulley for each, and they have a farther tendinous pulley between that and the claws. One part of the action of the paw is simply striking, much in the same way as the human arm strikes; and as the lion's blow is always what we call a back-handed one, it is sufficient to fell a pretty strong animal to the ground, or even to break its bones. It indeed tells with much greater proportional effect than the stroke of the human arm; for the lion has only a partial clavicle near the shoulder end, which is embedded in muscle, and terminates in cartilage, and therefore both in the lion's blow and in his pace the scapular comes partially in as a lever of motion; and in the direction of the mesial plane the paw of the lion strikes with three articulations; whereas, unless the weight of the body is delivered along with the blow, the human arm strikes only with two. There are some other advantages; the bone is of more solid substance than any other bone in the mammalia; and the system of muscles is remarkably strong all the way to the shoulder, at which place the mane of the lion preserves them from changes of temperature, and thus the first motion of the limb is, in proportion to its extent, remarkably free; and thus great velocity, as well as great weight and strength of matter, are given to this general motion of the limb.

It is only in so far as the muscular structure of the fore arm is concerned that there is the remarkable coincidence between the lion and man to which we have alluded; for though there is a similarity between the action of the lion's paw in clutching his prey and that of the human hand in grasping, the paw is

very limited in the kinds of action of which it is capable, as compared with a hand. It will be seen from the position of the pulleys through which the tendons of the flexor muscles (and they are the ones principally shown in the cut), that the general action in compressing the paw is a drawing of all the claws in the direction of the centre of the foot, by which means, though there is no reversible thumb, the claws, when they take effect, are capable of holding on against each other with the firmness of a crab. Great care is also taken that this apparatus shall suffer no injury from the weight of the animal, either in walking or in straining, while the foot holds on in rendering the prey. The balls of the toes which answer to the under sides of the knuckles, or balls of the fingers in the human subject, are amply provided with pads so large, so thick, and so elastic, that though the animal alights on them upon hard ground from his most vigorous and prolonged leap, the acting parts of the under side of the foot can sustain no injury.

The portion of the mechanism, however, which is most worthy of attention as illustrative of the structure of most of the carnivorous animals, is the claw itself, and the machinery by which it is worked. It is necessary to keep in mind that, in the human hand, in the lion's paw, and in the foot of every animal which has much motion of the toes, there are many muscles besides those which are situated on the fore arm. These last are as it were the large and rude parts of the machinery, fitted for strength of motion, but not for delicacy, and all the finer operations of the organ are left to the others. These secondary and smaller muscles which perform the delicate operations affect all the bones of the organ, the carpal bones, the bones of the metacarpus, and the phalanges of the fingers. In the human subject these muscles are exceedingly numerous, because of the motions, which, independently of the motions of the arm, the hand is capable of performing. The last two joints of the fingers have not, indeed, much lateral motion, for that would render them unsteady, but they have all a considerable degree of such motion on their metacarpal joints; while the thumb, different from the corresponding in even the handed animals, has such a motion on two joints, and is steady laterally only upon the last one. In consequence of this number of small muscles, and of the number or peculiarity of the bones to which they are applied, the actions of the hand are altogether beyond the power of numbers to express, and those smaller muscles become delicate in their action as they diminish in size, so that if they are not overpowered by the more habitual action of the larger muscles, the operations which the hand can perform are as nice as they are numerous. There is, however, this peculiarity in the hands as well as in every organ and every animal with which we are acquainted, that when one peculiar set of muscles is frequently and strongly employed, the energy of the organ or of the animal is habituated to that particular set of muscles, and all the rest become less capable of performing their function, than if the whole were equally exercised. The action of the lion's paw is a very limited action as compared with that of the human hand; but in proportion as it is limited, it is more energetic in all that it is capable of doing. This is in accordance with that general law of the animal economy to which we have had occasion so often to allude; and it is gratifying in the highest degree to find that a few very simple general prin-

cles are sufficient to carry us through so extensive and complicated a study as that of the organisation of the mammalia. We must, however, advert to the particular structures of the toes and claws of the lion, and the simple yet effectual manner in which they protect the instrument, and give it effect when it is required.

Upon looking back to the smaller portion of the cat, which represents a single claw upon a larger scale, and as it is situated when the claw is retracted so as to save its point, it will be observed that the last phalange or bone of the toe, except the one which immediately carries the claw, stands nearly perpendicular, while the bone which does carry the claw is applied obliquely upon the upper side of it. An elastic ligament which is applied to the bone just at the root of the claw holds it backwards and upwards, and the tendon of the flexor muscle which pulls this joint and depresses the claw, passes down the one side of the second bone across the bottom, and up the other side; so that this tendon cannot, while the bones are in this position, move the one upon the other. When, however the extensor muscles, which are the two whose tendons are marked uppermost, and which are inserted in the upper side of the head of the second bone, act with a powerful contraction, the opposite or under extremity of that bone is drawn upward by a very swift motion, and when that and the third bone are nearly in the same straight line, the joint supporting the claw is brought into such a position as that the tendon of the flexor muscle can obey its muscle, and depress the claw with great force. The claw itself is of a peculiarly strong form; and when the tendon of the flexor muscle draws it downwards, its point moves in the circumference of a circle, of which the centre is the same as that of the motion of its bone. When this takes place, the entire toe from the third bone to the claw is lengthened, because the three bones come much more nearly into a straight line with each other than in the state of repose. This is attended with a double advantage in the action of the claw; the pad on the second bone, which is shown of considerable thickness in the sketch, and which, as has been observed of all the pads on the lion's foot, secures the active structures at all times, is drawn upward at the very same time that the claw is descending. In consequence of this the advantage of the momentum gained both ways is given to the claw, and the point of it penetrates with much more force than would readily be believed. The pressure of the weight of the animal tends farther to elevate the pad, and while the joints are stretched, and the flexor muscle continues to act, there are very few animals that can shake off the lion, and the few that can do so are animals of great strength, great thickness of skin, and great power of action.

As both the extensor and the flexor muscles have their tendons passing through strong pulleys of ligament, situated near to each other on the wrist of the animal, the extensors spread the toes at the same time that they stretch them, and enable the ligaments to retract the claws. The flexors, on the other hand, while they stretch the distal joints, and protrude and bring down the claws, draw the points of them together. Both these sets of muscles act at the same time when the animal is strongly excited and springs with violence upon its prey; and as it bends the joints of the legs, and thus presses against the body

of the animal on which it is fastened, it retains its hold very much by the bending of the joints alone, and without any great waste of muscular exertion.

The whole of the cat tribe have this peculiar structure of the claws, though of course the strength, and also the violence of the action, depend in a great measure upon the size and spirit of the animal. It is not easy to say whether, in the entire action of these most formidable instruments of prehension, the lion, or the great tiger of the Indian jungles, deserves the preference upon the whole action. The lion is perhaps the more terrible animal of the two in one single effort, because the body of the lion is more compact, and his strength is more concentrated upon the anterior part. The tiger, on the other hand, is more elongated, more graceful, more lithe, more active, and perhaps requires, as estimating weight for weight, more prey than the lion does. There is an adaptation to the principal haunts of the animals even in this difference of the forms of their bodies. The lion is a lurker and lyer in wait for his prey as well as the tiger, and therefore he is to a great extent a bush and forest animal. But the country in which he is found in greatest vigour and perfection, approaches more to the character of a desert than that of the tiger, and therefore the lion performs more of his journeyings in stalking about, or prowling in bare places, than the tiger does. The tiger's favourite haunts are those jungles upon the rich grounds, where the surface vegetation is much more vigorous than it is on the lion's pasture, and therefore the tiger is unable to stalk about as the lion does. Hence he has to leap a great deal more, in beating about for his prey. His leaps too are more of an upward character than those of the lion, as he has to clear the tall grass and reeds with which the jungles are covered in the openings between the trees, and other very tall vegetables, which rise above the tiger. This habit requires a greater equality of strength in the fore and hind legs, than the single spring of the lion upon his prey, and also more length and elasticity of the backbone; and as we associate notions of elegance or gracefulness with this peculiarity of form, and also as the tiger is more richly coloured than the lion, we are apt to regard him as the more graceful animal of the two. Each of them, however, is sufficiently powerful for vanquishing any animal upon the upper part of whose body it can retain its hold. The pulling together of the clutched feet, which, though they tear and lacerate, have not cutting edges on their under sides, is attended with vast pain to the animal on which they fasten; and at the same time the very powerful teeth are at work rending and mangling its flesh, which operation is rendered more destructive and agonising to the animal, by the continual tugging produced by the wriggling motion of the strong neck of the spoiler. It is only a very strong animal which can afford to run even a very short distance under the weight and infliction of either of those animals; for the weaker ones are struck down at once, and not unfrequently have their bones broken to pieces by the force of the spring, and are thus killed without any action of the teeth. The strong manner in which the claw comes down, and the great action and weight of the paw, cause a single claw to act with such terrible effect that it is sufficient to fracture the skull of a man, even though the tiger springs over him and hits him in no other way. Indeed, when the weight and momentum of the animal are in this manner delivered upon a

single claw, that one claw necessarily tells with much more effect than if the animal were to alight on all the claws a once. In great efforts, the body is always delivered upon the middle claws of the fore feet before the others take effect; and thus it pierces like darts projected from a powerful mechanical engine, before it clutches, though the clutch very speedily follows the other part of the operation. The whole action of those more powerful of the carnivorous animals very much resembles the projection of a war-like missile, only it is more complete, and the animal is the missile and the engine at one and the same time.

This circumstance is worthy of some consideration, inasmuch as it shows us that lions, and tigers, and all the more powerful of the cat family, are not made for the use of man, neither can their vast but momentary exertions be in any way pressed usefully into his service. This is in strict accordance with the conduct of these animals, and the increase and diminution of their numbers, when man clears away the jungles and cultivates the field, their powerful inhabitants contend for a time; but are ultimately foiled by the intellectual resources of men in a comparatively low situation, if these are in sufficient numbers, possess sufficient activity, and live in that harmonious manner which constitutes the grand strength of human societies.

If, on the other hand, from war or any other of these causes by which the numbers of mankind are thinned, the strength of their union broken, and the jungle begins again to invade the once cultivated ground, the lion, the tiger, and the other ferocious animals, reappear and reassert their dominion.

Some others of the carnivorous animals use the feet partially as prehensile instruments; though generally speaking they do so for striking down or holding their prey rather than for tearing it, they do not therefore come strictly within the list of animals with true clutching feet. Their prehensile character

is in their teeth; and as we shall have to advert to them in noticing the systematic arrangement of animals, we should be involved in repetition, were we, in the mean time, to offer any thing more than a few hints of the most general description. None of the three sets of teeth with which to some extent or other all the more completely mouthed animals are

furnished, can be considered as instruments simply of prehension, without at the same time performing some other function to which, in fact, the prehensile action of the teeth is generally subservient. One of the most complete cases of this prehensile action which exists among the mammalia, is found in some varieties of the dog family; and those which have it in the greatest perfection, have always the muzzle short, the neck and those muscles which move the jaws very powerful, and they hold on with great desperation, so that one of them may be swung round and round by the animal on which it fastens without letting go its hold. One of the most remarkable instances of this occurs in the bull-dog, which has not merely the canines, but even the fore teeth, so formed as to retain their hold. The above figure, which is a sketch of a dog hanging on by the under lip of a bull, will be a sufficient illustration of this kind of action, which is, generally speaking, not a very creditable one to the parties by whom such dogs are employed.

Some of the weasel or marten tribe also hold on very desperately; but after all their bite is a wounding one, rather than merely prehensile. Some of the rodentia, as several of the rat family and others, can keep a firm hold; but they are biters. We cannot therefore consider teeth as coming very strictly within the class of organs whose leading office is prehension, though that is often part of their office. There are few animals which have the teeth more prehensile than the cat family, and yet they are, in addition, furnished with the most complete instruments for catching prey of which we have an example in the animal kingdom. This is enough to show that the mouth of no animal alone is capable of finding a subsistence for its owner in the flesh of animals of any considerable power. In their other functions, whether of cutting, of wounding, of tearing, of bruising, or of grinding, the teeth of animals are to be considered more in the character of preparers of the food for the stomach, than of mere takers of it; and as in this point of view they form the basis of much of the classification, according to the best informed and most judicious systematists, they properly belong to that branch of the view which we have endeavoured to take of the mammalia. The canines of some of the pachydermata form the most decided exceptions to this; and these exceptions are found in animals which differ not a little in the nature of their food, and their digestive organs. Of these, one of the most remarkable is the hippopotamus, whose prehensile teeth are very strong, and covered with a more compact enamel than the teeth of almost any animals. The whole mouth of this animal is indeed a rugged and most formidable looking combination of parts; and if we were to judge only from the size of the jaws, and the development and texture of the teeth, we should be very apt to conclude that the hippopotamus was one not only of the most formidable, but of the most carnivorous animals in the whole class of the mammalia. When however we examine the feet, and see their perfectly harmless structure, and the internal parts, and discover that they are equal to the digestion of even dry sticks, we come at once to a very different conclusion, and do not fail in determining that like the other great animals of the same order, whether living or extinct, the hippopotamus is a dweller in peace with his kindred mammalia, and with all living creatures; and that,

though his means of defence against attack are exceedingly powerful, he wages no offensive war except against the vegetable kingdom. Even there, though he is not a welcome guest in cultivated countries where crops are grown close to the banks of those rivers from which he never wanders very far; yet in that wild and exuberant state of nature, which alone is compatible with the existence of the elephant, the rhinoceros, and those powerful animals of the order which are now gone, he is as completely in his place, and as useful in the system of nature, as the most graceful animal which roams the plains or browses the meadows. The tusks of the hog are another of the exceptions; and though when attacked this animal can inflict desperate wounds by means of them, their object in the natural economy of the animal is not that of wounding, but of tearing other substances than the flesh of living animals.

We cannot, however, come to any specific conclusion respecting the teeth of this order of mammalia; for whether the series was or was not complete at some former period, it is now so broken, and there is so little correspondence between one genus and another in this respect, that we cannot make a transition; and this is the reason why Cuvier, notwithstanding his profound knowledge of animal structure, and the agreement of the parts and the system with each other, was obliged to found the character of these animals upon the thickness of the skin, which is wholly of an external kind, and furnishes no guide whatever to any part of their economy, either as to what food they eat or how they procure it.

Respecting the digestive system of the mammalia, there are but few general remarks which can be made apart from those which are the foundations of the classification. It is obvious that the organs of digestion must be adapted to the nature of the food; and that therefore they must in a great measure correspond with the teeth, which are adapted to the same purpose.

The general principle is that the coarser the ordinary food of the animal is, its organs of digestion are the more enlarged and complicated. This however forms a sort of guide, though rather a loose one, to some points in the progressive history of the mammalia. The larger pachydermata are, for instance, adapted to a state of things in which vegetation is rank and coarse; and this again points to a humid condition of the surface of the earth, at least in the places inhabited by those animals. But the remains of such animals have been met with in almost every region of the world where men have had an opportunity of exploring the soil; and this leads us to the conclusion, that at some former period of its history, the earth must have abounded much more generally with water, both stagnant and running, upon the surface of the land than it does now.

We might even go further than this, were it not that it would involve us in a more extended history than that of the mammalia, and not only so, but lead us to the consideration of departed races of vertebrated animals, both swimmers and fliers, and some perhaps capable of performing both these motions, to which there is no likeness, or near approximation to a likeness, in any known animal which is now found alive. The farther investigation of this point, curious though it be, thus belongs to the general history of animated nature in its progress, or more strictly speaking to the progressive history of the

globe itself, than to the history of any particular class of existing animals.

Next to the pachydermata, the animals which have the organs of digestion the most elaborate and enlarged are the ruminants, of which we shall have to say a few words afterwards; and as they have a double labour to perform both with the mouth and the stomach, part of the enlargement is of necessity taken up by this doubling. The ruminants belong to a different state of things from the pachydermatous animals; although, as both are vegetable feeders, they have a slight approximation to each other on the confines. The ruminants belong to an era of more humble, but more kindly vegetation than the pachydermata; and therefore they appear to have come later in those places of the earth where both have inhabited. Not only this, but the species or varieties which are found only in the earth, are larger than the existing ones of the same places. It is true that in several instances the domesticated varieties are often larger than what we may consider as being the extinct natives. We can, however, draw no safe conclusion from this with regard to the natural progress; for where man cultivates, he always brings a more rich and succulent vegetation over the soil, than that soil would yield without the benefit of his labour, unless in places where the natural tendency is to be overrun by forest trees, or by brushwood.

In proportion as the food of the vegetable feeder begins to partake more of the pulpy or farinaceous character, the organs of digestion become smaller and simpler. In the miscellaneous feeders they are still more so, and the decrease becomes more and more, according as the food becomes more and more animal.

It is not very easy to say what particular states of countries are best adapted for those animals whose food differs but by small shades, and which can in consequence turn readily to one when another fails.

When we come to the carnivorous animals, we must attend to the nature of their food, and the means they have of catching it; and as the more powerful ones prey chiefly upon vegetable feeders, we are sent back again to inquire what condition of the earth's surface is best adapted for furnishing an abundant supply of these. Thus when we attempt to turn the mammalia into an index to the progressive natural geography of the earth, we find that there are some doublings which carry us back very nearly to the point at which we set out, and by this means involve us in difficulties from which we are unable to escape.

The remarks which we have made in this section, and in which we have endeavoured to select the most characteristic animals, and speak of the leading functions of their organs, must suffice for this highly interesting branch of the study of the mammalia, which is, in a great measure the key to the philosophy of the whole.

SEC. VI.—CLASSIFICATION OF THE MAMMALIA. —There is no branch of natural history which has received more improvement at the hands of the leading naturalists of modern times, than classification; and though this may seem to be but a humble branch of the subject, it is not so in reality, at least when founded on views sufficiently extensive, and pursued in the spirit of candour and discernment. In theoretical proof of this we need only remark, that the best classifications of animals, to which part soever of the kingdom they belong, have always been projected

by naturalists of the greatest talent, and most general acquaintance, not only with every department of the animal kingdom, but with the relations which subsist between that kingdom and the other parts of the material creation.

There arises an argument from the practical utility, which completely bears out this theory, and also points out, not the advantage merely, but the absolute necessity of every one who would wish to profit by the study of animated nature, grounding himself thoroughly in the principles of classification.

It is true that empirical grounds of classification have been proposed in times comparatively recent; and that by men who have made a great deal of noise, and obtained an ample share of temporary notoriety, if not of permanent fame. While the one of these lasts it requires a good deal of penetration, exercised by one who is not a follower of the multitude, to see the distinction between it and a scientific one; they pass with the million as having equal merit; and as the man who proceeds upon his own fancies always fights for them with more zeal and clamour than any man exercises in the cause of demonstrated truth—feeling that it can maintain its own ground without support—the majority of the multitude invariably, or at least in the majority of cases, follow the impostor during the day of his vapouring, and leave true science to steal on with that unobtrusive meekness and steadiness of march which have ever been its concomitants in all its ways. The cause of the success of imposture, or folly—for it is much the same in effect, whether the party imposes on the crowd at second hand, by first imposing on himself, or whether he imposes on them at first hand, he himself not being under the influence of the imposition is obvious enough. There is a *moral* distinction: but we are not speaking of ethical principles, but of the common philosophical succession of events in the order of cause and effect; and thus far, if the effect produced by one who imposes first on himself and then upon others, and one who only imposes upon others, be exactly the same, the causes, how different soever they may be in a moral point of view, are perfectly equal in the judgment of natural philosophy, or of simple philosophy of any kind, with which moral considerations are in no ways mixed up. But to return to the subject with which we are more immediately concerned.

If there is to be any use in classification, it is nothing more than an enumeration of the relations in which the subjects classed stand to each other, and their agreements and differences. In the classification of any one branch, whether large or small, of the productions of nature, regard must be had to all the rest; for unless the reciprocal influences which they exert upon each other are known, we are ignorant both of the natural use, and of the application which we might be enabled to make of that use.

This is the reason why so extensive a knowledge is required before any one can venture to form an arrangement, and therefore if statutes for regulating the modes of knowledge could be introduced without any of the drawbacks and mischiefs usually connected with statuteness, it would be no bad law to compel every projector of an innovation to prove that he were more competent than the founder of the classification upon which he sought to innovate. Such, at all events, would spare the world the trouble of a

whole host of small innovators, who are constantly splitting hairs about genera and species, and waging stern war upon some such most important point, as “Whether a black nose and a grey constitute different species, different varieties, or merely point out different stages of growth in the same animal; and also whether a black nose or grey nose has made the nearest approach to those years of discretion, in the bloom of which the disputants believe themselves to be wantoning.”

So much time is wasted upon matters analogous to those we have now mentioned, among the junior labourers in the field of natural science, that the subject assumes an importance, in a precautionary point of view, to which its intrinsic merits would never entitle it; nor is it altogether unamusing to observe how these doughty disputes fine away, like the tail of a streak of curl-cloud, till they melt into thin air. They put one strongly in mind of the ultimate argument of the one grammarian to the other, which is recorded to have been adduced at the end of a long and wordy disputation on the grave question as to “Whether the implied nominatives of impersonal verbs are *entites* or *quiddities*?”—“The lord confound thee for thy theory from personal verbs!” said the enraged grammarian; and at this point both language and logic broke down, so that there was a final end at that time, and the question remains as ready for fresh disputation as ever.

As we have said, the classification of natural subjects of any kind ought to be so framed as to involve their uses as much as possible, and this is the reason why a system grounded on the general organisation of animals is so superior to every other. The mammalia, as having their organisation the most complete, afford the best means of obtaining an understanding of the principle; and considering these, the system of Cuvier is superior to every other which has been proposed. The discovery of new species, and a more intimate acquaintance with the structure and habits of those which are but imperfectly known, must of course lead, and has in fact already led, to minor changes—such as the transfer of a few animals from one part of the system to another. In all this, however, there is nothing by which the fundamental principles of Cuvier's arrangement have been, or apparently can be, substantially shaken, at least until much further discovery has been made in the science.

The great skill and the unwearied industry which Cuvier brought to the investigation of the structures of animals, and the fact of his taking the extinct as well as the existing, in so far as the evidence enabled him, placed him on a vantage ground which no previous classifier had occupied. Ray perhaps came the nearest to him; and, like Cuvier, he studied long before he ventured to put the knowledge he had acquired into a scientific form. Ray laboured, however, under the disadvantage of having but scanty materials as compared with the other; and therefore, though it is impossible to study his works without great profit, as well as great admiration, the labours of Cuvier are much better calculated for bringing the subject readily, clearly, and speedily before the reader. So that if any one wishes to be a naturalist, especially a student of the mammalia, the “*Règne Animal*” is the indispensable text book. Indeed, it possesses an advantage which few, if any, other text-books possess. Such books, whatever may be their subject, are, generally speaking, artificial memories of

individual facts, and for this reason they are books of reference rather than books of instruction. The "*Règne Animal*," on the other hand, is a systematic arrangement of principles, generalised with the greatest skill, and often carrying the single glance so far that the reader is astonished at the volume of light which he receives in comparison to the small number of words by which that light is produced.

In saying this, we do not mean to assert that the system is perfect, even in the mammalia, which have been more carefully examined, and are therefore more easily classified according to their structures, than any of the other classes. The arrangement has, as we have already said, both breaks and doublings in it; and thus there are intervals to pass over and returns to make which break its continuity; so that even in the arrangement of Cuvier, we cannot view the mammalia as one continued class, proceeding from man, subduing and improving the earth, to the toothless whale careering through the wide ocean, though these two may very properly be considered as the extreme limits within which all the mammalia are contained.

A little reflection will, however, show us that this is exactly what we ought to be prepared to expect. The mammalia differ, and differ greatly, from all the other productions of nature; but they do not stand independent of the rest at any one period, or remain permanent in themselves for perhaps even two consecutive moments, though time is required before the changes which they are undergoing are sufficiently great for coming within the range of our observation.

The discoveries which have been made by geologists, and the investigation of those more powerful causes which operate upon the mass of our globe, and in all probability cause sea and land to alternate with each other after long periods of time, come in to disturb our generalisations, and occasion breaks in the system which we have no means of filling up. When an old land has performed its function, and become like an old tree or an old animal, unfit for the further performance of it, the hand of death passes over it, and it is of course lifeless, plantless, streamless, worn into sand, and literally, in the language of the sacred volume, "sowed with salt." Then of course it is fit for burial, and sinks down into the great laver of the ocean, in order to be regenerated. By the same action which gathers the exhausted land to its tomb in one place, we may naturally suppose that, to preserve the economy of the earth as a globe covered with land and water, new land is raised up in another place, and amid changes more mighty than we can well comprehend, the stability of the planet remains unshaken.

But here we touch the extreme bourn of human philosophy, and are unable to tell either whence the plants and the animals of the new land come, or how they differ from those of the old one. Whether amid those mighty revolutions which shake and wrench the solid globe to its centre, yet without in the least disturbing the stability of that which remains as true to the solar influence, the major axis and the orbital of motion, as when all is tranquil;—whether amid these, "the Spirit" again "moveth on the face of the waters," and they "bring forth abundantly," so that the new land rises up planted and peopled, and ready for setting forth the wisdom and the power of the Creator in the life and enjoyment of its creatures, we

cannot—we even dare not conjecture. We have evidence, however, that very large portions of the now-existing land upon our globe have, in the olden time, been very differently planted and peopled from what they are now, and not only so, but that there is a series of changes, in both of which we can tell the succession in the order of time, though we cannot form a guess at the length of time as applicable to any one of them.

The result of all this necessarily is, that our existing mammalia, which we are called upon to classify, form a fragment, or rather perhaps a number of fragments, each of which has belonged to a former state of things; and this result ought to satisfy us that we spend our time in vain if we attempt to make any thing like a perfect system of any one of the kingdoms of nature. After these preliminary remarks, we shall proceed to give an outline of the system of Cuvier.

The successive divisions established by those naturalists who knew but little of the difficulties arising from the fragmental nature of the living mammalia, were orders, genera, and species, which last admitted of varieties; and they made the transition from the class to the order, from the order to the genus, and from the genus to the species, all of the same nature and extent as if they had been uniform throughout the whole class. Cuvier has retained those established names as expressive of his principal divisions; but we must not suppose that one who was so capable of proceeding according to the organisation, as expressive of the habits and use, and who was warped by no theoretical notion before the facts, could have failed to perceive those irregularities to which we have alluded—irregularities which will perhaps one day require a breaking down of class, order, genus, and species into two or more parts, differing less than those do from each other, and thus enabling the system to take one more step toward perfection. Cuvier himself has in effect done this; for though *he*, at least—setting far more value upon the enunciation of truths than the enumeration of names—is never dogmatical in fixing what shall constitute these minor differences, yet he does not hesitate to group those formerly described genera which have too general a similarity of structure for admitting of palpable generic differences, or to separate those between which the structural differences are too great for their standing properly in the same genus.

These are apparently minor points, but it must not be supposed that they are unimportant ones. What is the use of a generic name, and an enumeration of generic characters, if those characters do not apply to every species contained in the genus; at least in all those points over which climatal and other accidental causes have no controul? On the other hand, what is the use of two generic names, and two enumerations of generic characters, if the animals are alike in all those permanent points of their characters over which climate and other external causes have little or no controul?

It is the adaptation of the characters to every animal to which the name applies, and the restriction of it to those animals, as well as the restriction of those animals to it, which constitutes the merit of any name given to a group of animals, whether that group happen to consist of few or of many; and this is best obtained, and indeed can alone be obtained, by not founding the distinctions upon particular organs, but

on the organisation generally, and the habits indicated by that organisation. The reason of this must be apparent to every reader ; we want the name as a correct index to every thing named by it, as by this means, and by this means only, we can apply our knowledge of the known animal to the unknown one, and thus acquire the knowledge of it at once by analogy. If this be not the use of systematic arrangement, it does not appear likely that we shall discover any other.

It is probable that from respect to the existing authorities, who had of course been his schoolmasters in the elements, as well as from that dislike of ostentation which is inseparable from genuine talent, Cuvier made fewer changes in the nomenclature than he himself could have wished, or at least saw to be necessary. Upon a careful examination of the characters of the mammalia, as given by himself, it will be seen that some of the orders as he has left them, and even the class itself, admit of subdivision. The fundamental character of the class does not apply, at least in the same manner, to the placental and the marsupial mammalia. Then again, if there is to be any uniformity in the system, the marsupial ones cannot by any means be brought within one order, according to the general and the best foundation upon which orders can be grounded—the systems of their arriving at their food and feeding ; because these animals inhabit different sorts of places, live upon different sorts of food, and collect that food in different ways and by means of different instruments. Even among those mammalia which are all regularly placental, there are some orders which would require subdivision, because a character properly expressive of no one of them would apply to another one with equal propriety. These distinctions will be better understood, however, when we come to the enumeration of the orders in which they occur ; and we shall now mention their names, and offer a few remarks on them, in that succession in which Cuvier has arranged them.

There are in all nine orders : *Bimana*, or two-handed animals, of which man is the only instance, and we have no reason to believe that there ever was a different genus, or even a different species of this order, which stands alone upon peculiar grounds, which we have already explained at some length ; *Quadrumania*, or four-handed animals ; *Carnassiers*, or feeders wholly or chiefly upon animal substances ; *Marsupialia*, or animals in which the females are furnished with an abdominal pouch, more or less developed according to circumstances ; *Rodentia*, or animals which have the mouth formed for gnawing, and of which the greater part live wholly or chiefly upon vegetable matter ; *Edentata*, or animals in which the teeth are defective or wanting ; *Pachydermata*, or thick-skinned animals ; *Ruminantia*, or animals which chew the cud ; and *Cetacea*, or the whale race.

BIMANA.—So much has been said in former sections respecting the general character, structure, and functions of man, that it would be quite superfluous to make any addition. As we have already observed there is only one species of mankind, though there are various races, differing from each other in the external appearance, and also in the forms of some of the bones, but all capable of breeding with each other, and having offspring which is just as fertile in the cross as in either of the races, and no greater tendency to breed back to the pure blood than to

breed with exactly the same cross, or even into a new race. This is perhaps the most decided evidence we can have of sameness of species ; and so when we find that it holds universally, any attempt at subdivision would be unphilosophical. We have also said, that there is no evidence whatever of any extinct species of *bimana*, or of any having existed in those remote times when the general vegetation of the earth was different from what it is now ; and this leads us to connect the human race with the existing state of things only.

This is by no means an unimportant fact in the history of the world, or in reconciling the results of geological discovery with the history of the human race as it is recorded in the Bible anterior to the commencement of other histories, which, however, when they apply to the same subjects, always strengthen the evidence of its truth. In the sacred volume it is stated, that the earth was prepared for the reception of man, by being covered with vegetables and stocked with animals before he was created, and that the creation consisted of a single pair only. This perfectly agrees with the physiological fact of any perfect pair of the human race being still capable of, in time, peopling a country.

There is, in the shadowy and brief account of creation in the book of Genesis, something which agrees better with the supposition that new lands are successively elevated from the sea as old ones are worn out, than we should have been prepared to expect, or than would have been believed before the monumental treasures of the earth were so well explored, or the strength of those powers which are contained in the earth were so fully investigated and tried. The earth (meaning thereby the dry land, in contradistinction to the water) “without form and void, and darkness covering the face of the waters,” is exactly the state of things that would be produced, if the terrible exertion of the internal forces were upheaving a continent from the depths of the Atlantic or the Pacific. The action of a single volcano, and that not to any very great extent, has been known to render the atmosphere and the earth under it well nigh as black as midnight for a considerable period of time. The space of action in these cases is generally small as compared with a single mountain, and a mere nothing when contrasted with a continent ; and if we suppose that the laws of nature are not broken even in the most violent natural action, which is the only supposition that reason can make, we must be prepared to admit that the darkness arising from the ascent of a continent might be deep and durable beyond any example that we can have in the action of ordinary volcanoes. In those actions of submarine volcanoes which raise islands above the surface of the water we have displays which are sublime beyond those of the land volcanoes, because of the great additional action produced by the decomposition of water and the combustion of its hydrogen. The quantity of aqueous vapour produced upon such an occasion as that to which we are alluding, would fill a vast extent of the air with vapour of water. This vapour of water would, upon the well-known fact that when salt water is evaporated the salt does not rise along with the vapour, furnish an abundant supply of fresh water for filling all the hollows of the new made land, as soon as that land was so cool that the vapour could descend in rain ; and thus we have an ample provision for lakes and rivers, in the very fact of the new land

being raised from the bottom of the sea by the action of internal heat in the earth.

We are not speaking of what actually did happen, because such a scene as we are alluding to could have no material eye, and no organised being present at it, unless that organised being were so deeply buried as that the pressure over it were capable of restraining the tendency of its volatile parts to escape. Still it is important to see that there is no violation of observed fact, philosophic theory, or rational probability, in what we have now been stating. On the contrary, the facts are strongly in favour of it. There has not been explored, upon the whole surface of the globe, a single district of rugged surface in which there has obviously been in the early time a wrestling of some giant power with the rocks, in which there are not numerous instances, almost innumerable ones, of lakes which have been emptied of their contents by the wearing away of their inclosing dams during the lapse of time; and the progress which the fall of Niagara has made, and is still making, in cutting the rocky barrier, points to a time within reasonable probability when the great lakes of America shall be poured forth through the valley of the St. Lawrence, and the character of the country totally changed. The disintegrated beds of substance which have once been rock point to changes produced upon a surface which came ragged and uneven from the bottom of the deep; and as such a surface could not but remain plantless for some length of time, in which way soever we are to suppose vegetation to have been established in it, the great influence of the sun in heating and cooling the naked rock would vastly increase the quantity of evaporation from the pools and lakes in the hollows; and thus the rains would beat, cascades would dash, and streams would roll upon such a surface, in a style of violence of which we of course can have no idea, though we do know that when lakes alternate with dry rocks the quantity of rain is increased to an astonishing amount. No small portion of the western coast of the Scotch highlands, and many of the isles, are of this description; and so habitually does it rain, that visitors from the low country are in the habit of saying that it sometimes rains "eight days in the week"—the eighth day consisting, of course, of the weariness produced by the continual pelting or dripping of the seven.

We shall not pursue this investigation any further, because, though it bears very closely upon a most important point in the natural history of the human race, it is in great part conjectural, and does not in any part belong to the *present* natural history of any race of organic beings, animal or vegetable. The probability is, however, that there has been no violent general change of the earth since it was the abode of man; and though we know not the period which might be required to prepare it for the reception of the single pair, physiology supplies us with no reason for concluding that any more than a single pair of human beings was necessary for peopling it. More indeed would have been superfluous, and superfluity is no attribute of nature's working, whether on the great scale or on the small.

The difference of races is another matter, but it is one of minor importance; and one of which we find explanations, or at all events illustrations upon a small scale, every where around us. Human beings of the same country, of the same district, and even of the same family, are more diversified than any other

animals. There are also, notwithstanding this individual diversity, likenesses which run through families, through clans, through districts, and through all associations of human beings which are much together, following the same occupations, and having similar opinions and habits.

Such being the case where we cannot fix upon any external cause for the difference, and in instances where the likeness extends only to two generations, we may be prepared to look for much greater differences when the differences of climate, habits, food, occupation, and many other things are very strikingly marked. Perhaps the best short account which we have of the original races of mankind (for they are not species, or even varieties, in the ordinary sense of these terms as applied to the rest of the mammalia) is that by Baron Cuvier, and therefore we shall give it with as much condensation as the language of so concentrating a writer admits of.

"Though," says Cuvier, "the whole human species are one, so that all the individuals can mingle together and produce fertile progeny; yet we can observe among them certain hereditary conformations, which constitute what are known by the name of races. Three of these are eminently distinguished above the others: the white, or Caucasian; the yellow, or Mongolian; and the black, or Ethiopian.

"The Caucasians, to whom we belong, are distinguished by the elegant oval form of the head; and they have given birth to the most civilised nations, or to those who have most frequently ruled the others. They vary much in the complexion and the colour of the hair.

"The Mongols are known by prominent cheek bones, narrow and oblique eyes, a scanty beard, straight black hair, and an olive complexion. They have formed the great empires of China and Japan, and often extended their conquests to the south side of the great desert; but in point of civilisation they have remained nearly stationary.

"The Ethiopian, or negro race, are confined to the southward of Mount Atlas. Their complexion is black, their hair crisp or woolly, their cranium compressed, their nose flattened, their jaw bones projecting, and their lips large and thick. They have remained in a state of comparative barbarism.

"The Caucasian race are so named because tradition generally refers their origin to the mountains of Caucasus, between the Black Sea and the Caspian; and the Circassians and Georgians are still accounted the most handsome people in the world. The different branches are known by the analogy of their language. The Armenian branch proceeded southwards, and gave origin to the Assyrians and the wild Arabs, which, after Mahomet, remained for a time nearly masters of the world. The Phœnicians, the Jews, the Abyssinians, and the ancient Egyptians, belong to the same source. This branch has been always prone to mysticism, and has given origin to some of the most widely extended and permanent religions. They have often promoted science and literature, but the former always tinged with mysticism, and the latter clothed in highly figurative language.

"The Indian, German, and Pelasgic branch has extended much further than the others, and separated at an earlier period. Still there are numerous analogies traceable between its four principal dialects—the Sanscrit of India; Pelasgic, the parent of the Greek, the Latin, and all the ancient tongues of the south of

Europe; the Teutonic or Gothic, the parent of the German, the Dutch, the English, the Danish, the Swedish, and other tongues of the north-west; and the Slavonian, from which the Polish, Russian, and other tongues of the north-east of Europe, are descended. This branch have been generally admitted to stand foremost among the human race, having excelled all others in the arts and sciences, of which they may be said to have been the depositories and guardians for thirty generations. Previous to their arrival in Europe, it was occupied by the Celts toward the north, and the Cantabrians from Africa in the south; but these branches are now reduced within very narrow limits. The ancient Persians, as well as the Indians, belong to this branch.

"The Scythian, or Tartar branch, went at first toward the north-east, and lived a wandering life in the vast plains of Siberia. From these they often sallied forth, carrying conquest and desolation over great part of Asia. The Huns and Finlanders are hordes of these people, which have strayed in between the Goths and the Slavonians; but on their eastern confines they are blended with Mongols, who inhabit next to them in the north of Asia.

Of the Mongol race the Kalmucks are still nomadic in the deserts. They have at times been powerful in their own country, and their warriors have carried conquest and terror into other countries. In the Japanese and Chinese, and also in some nations in the centre of Asia, these people have often displayed great civilisation and industry, and very delicate execution, though with much peculiarity of taste, in the arts."

It is not easy to determine when the inhabitants of the south-east of Asia, and of the shores of the greater islands, and also of many of the small and remote ones in the Pacific, had their origin; and the origin of the negroes of the centre of those islands, and of the extensive islands of Australia, who have perhaps made less progress in civilisation than any others of the human race, is equally obscure. The Malays, or first of these races, who are very adventurous on the sea, probably found their way from the south-east of Asia. The origin of the Americans is not well understood. In some points of their aspect they bear no inconsiderable resemblance to the Malays, but in others they differ.

Around the extreme north both of the eastern and western continents, there are diminutive races, which content themselves with the most humble fare, and live in a state of what would appear to us great misery and privation; their origin has never been clearly ascertained; and indeed much of what has been said, or can be said, upon the subject of these races, is either purely fanciful or merely tradition. The analogy of language has often been drawn upon as affording a clue to the affinities of the various branches of those races; but such an analogy is a very treacherous guide in matters of this kind. It is to be borne in mind that only a small portion of the language of any age or nation can be transmitted from generation to generation, unless by means of a written literature pretty copiously distributed among the people. We have evidence of this in the difficulty with which the older writings in the English language can now be read; and if we are to suppose a language to have no stationary means of permanence, its changes in the lapse of time would of course be much greater. In every light in which we can

view the matter, indeed, the progressive history of the human race is attended with insurmountable difficulties; and almost the only general conclusion, beyond actually written history, at which we can arrive, is, that the race is substantially and originally one, notwithstanding the various aspects of the tribes and nations of which it is now composed.

QUADRU MANA. These form the second order in Cuvier's arrangement; and, as has been already explained at some length, when treating of organs of climbing, the character of the order is that of having all the four extremities prehensile, or capable of laying hold. The prevailing character of the whole race is the facility with which they can grasp, and the next is the power with which they can grasp in proportion to the size of the grasping instrument. We have said so much respecting them in the course of the article already, that it is unnecessary to repeat any of the details. Cuvier divides them into three groups, or sub-orders; and some of these contain a greater and some a less number of genera. The apes of the old continent form one branch of the first sub-order, and the apes of the new continent another, though in common language the small ones are all known under the common name of monkeys. The remaining groups are the ouistitis and lemurs, of all of which, as well as of the apes, monkeys, and baboons, details will be found in the general articles headed by their names, or in the particular articles referred to in them. The whole of this order are forest animals, inhabiting only the warm parts of the world; and they cannot be regarded as being in any way useful to man, or advantageous in any place which he cultivates. It is not fully ascertained whether they belong exclusively to the present state of things to which, as we have said, man appears altogether to belong; though it is highly probable that such is the case, as they do not belong to a kind of vegetation corresponding to that which must have existed when the pachydermatous animals, which are now extinct, were inhabiting the earth. No remains of any of them have hitherto, in so far as we are aware, been found in the fossil state, though it is not improbable that some may occur in the collections of rubbish which have been brought together by the rain floods of those countries in which they are at present so numerous. Altogether, they are a most useless and even offensive order, though their great powers of motion among the branches, and their ludicrous though rather slight and fancied resemblance to human beings, make them objects of interest to those who look upon natural history as a matter of curiosity rather than of use.

CARNASSIER. This is the third order, and it is a far more interesting one and far more extended over the world than the second order. The word "carnassier," though it has very nearly the same meaning as the word *carnivora*, has not been introduced by Cuvier without some advantage, because it accords better with the common use of language. We associate the name of a carnivorous animal, or "a beast of prey," with the notion of an animal which, by chase or by stratagem, seizes other warm-blooded animals in the living state, kills them by instruments fitted for the purpose, and eats their flesh; whereas there are numerous animals, properly included in Cuvier's great order, which do not kill warm-blooded animals; and there are a few which live in great part upon vegetable matter.

The general characters which run through the whole order are, the toes of the foot well developed; but without a thumb opposable to the toes; and they have all three sorts of teeth—incisors, canines, and cheek teeth; the second in general so produced that they act not sufficiently in wounding and killing, and the third variously formed according to the nature of the prevailing food of the animal. They all live, in part at least, upon animal substances; and those which do this the most exclusively have their cheek teeth with the most trenchant or hatchet-like edges, so that they can readily cut asunder the flesh of animals, when it is in the recent state, and cannot readily be divided by a simple bruise. Those which have some of the cheek teeth at least with tubercles on the crowns, live more or less upon vegetable matter, though upon matter of a more succulent and nourishing description than that which forms the food of the genuine and habitual vegetable feeders. Those again which have the cheek teeth beset with little sharp points on the crowns, feed more exclusively upon insects, and other small invertebrated animals; though there are some even of these last which are especially ravenous in the true carnivorous way, until they become cannibals, after a violent struggle for the mastery. Even those which occasionally feed on vegetables have no lateral or grinding motion of the jaws, so that they have no means of reducing fibrous vegetable matter to anything like a pulp, so as to prepare it for the single and simple stomach with which they are furnished. The quadrumana, as well as man, have a motion of this kind, so that they can grind the food by rolling it between the cheek teeth; whereas the carnassiers can simply close their jaws upon it, without any means of dividing it. This reduction of the action of the jaws to one plane, concentrates it more than in those animals which grind their food; and thus their direct bite is more keen and steady in proportion to the degree of muscular energy exercised in producing it.

The brain in these animals is better developed than in any of the orders which follow them; but still the cerebrum is without the third lobe, and it does not form a duplicature over the cerebellum, as is the case in man and in the quadrumana. There is also no septum of bone between the temporal fossæ and the orbit of the eye. Their skull is also much more compressed in proportion to its length than that of the quadrumana, even such of them as have the muzzle produced by a lengthening of the bones of the face; but though these forms of organisation are different from those of the quadrumana, we must not thence conclude that the animals themselves possess less animal sagacity, or have fewer resources. The want of the third lobe in the brain appears to have really more connexion with the absence of the power of grasping, than with that of animal sagacity; for some of the carnassiers are exceedingly cunning in a state of nature, and others are capable of more education than almost any other animal, and can be made to perform work, and valuable work, which could not be performed by any ape, and not even by man himself. A dog will find his master when no human inquirer can; and a blood hound will track that upon the slot of which he is sent, with a certainty and a perseverance which is perfectly inexplicable upon the principle that regulates the animal functions of man, and even by mind itself.

The other differences between the carnassiers and the quadrumana, are not to be regarded as fallings off of development in the latter, any more than the difference in the brain to which we have now adverted. The absence of septa, or partitions of bones between the temporal fossæ and the sockets of the eyes, gives the animals an increase of power, instead of a deficiency. By this means, they are enabled to have the eyes placed more laterally, so as to command a more extensive horizon without turning the head, and the absence of the partition and the elevation of the arch gives more room for the origin of those powerful muscles which move the jaws. Generally speaking they have clavicles more or less perfect; and they have a rolling motion in the elbow joint, so that the extremity of the fore foot commands an extent of motion in the cross direction, as well as in the backward and forward one. They are also less loaded with the organs of digestion than even the quadrumana; for the food being in most instances of a much more nourishing nature, they require less of it, and do not retain the parts unfit for assimilation so long within the cavities of the body. Simple as this last peculiarity may seem, it is attended with considerable advantages to the animals. They have to seize their food with more exertion than the other mammalia, as they have generally speaking to catch and kill before they can eat. They, therefore, require that a larger portion of their weight should be applied to external action, and a less portion to digestion; and it is a beautiful provision of nature, that the food of these, and indeed of all animals, should be nourishing in proportion to the quantity of muscular exertion which the animal must exercise in order to arrive at it. The nourishment, and the capacity of undergoing the exertion, also harmonise with each other. In proportion as the muscular system of an animal is exerted, a supply of arterial blood is required. This supply cannot be obtained in a wholesome state unless there is some chyle to mix with the returning blood ere it is sent through the heart to the lungs in order to undergo the purifying influence of atmospheric air. This is the reason why people in an extreme of hunger wax faint and are incapable of muscular exertion; and it is also the reason why the derangement of the digestive organs should have so enfeebling an effect on the muscular energy of the body, or upon the spirits, as we say in common language. The discovery that these very simple and very general principles run through the whole system of nature, is one of the greatest encouragements that we have in the study of natural history; because it shows us that no one subject which we can study has its instruction confined entirely to itself; but that on the other hand every portion of knowledge which we can acquire, at once becomes the instrument of additional knowledge which we can use with equal readiness and success.

The carnassiers, to the extent to which Cuvier carries the order, and notwithstanding the differences which prevail among the genera and species, the order is a very compact and complete one, and renders a subdivision into suborders or families necessary; and some of these suborders are so numerous that they admit of a farther division into groups before we come to the genera. Cuvier's first sub-divisions are the *Cheiroptera*, or bat family; *Insectivora*, or those which live chiefly on insects; *Carnivora*, or those

which prey most extensively and exclusively on warm blooded animals.

CHEIROPTERA.—This family consists of two genera, the great genus of the bats, and the *Galeopithecus*, which is not a flying animal as the bats are, though it resembles them in some parts both of its organisation and its habits, and is furnished with a leaping membrane or parachute of ample dimensions. The details of the structure and action of the bats have been already given in the section upon the flying organs of the mammalia; and some notice of the species, and some popular accounts of the habits, will be found in the article BAT, and the article GALEOPITHECUS.

The second family, or the insectivorous ones, are almost, if not altogether, nocturnal animals which live in and often under the ground; and most of those which inhabit cold countries, hybernate or pass the winter in a lethargic state. They feed chiefly upon insects and other small ground animals, and thus their teeth in the posterior part of the jaws are of the insectivorous character. The nature of their food renders it necessary that they should hybernate during the inclement season; because at that time the insects of such countries are gone, and the other ground animals have plunged to a considerable depth below the surface. Those which dig habitually in the ground are furnished with a keel upon the sternum in the same manner as the bats: they are also all provided with clavicles, so that the cross motions of their fore legs are powerful in proportion to their size; the hind ones, on the other hand, are often feeble, and what with the feebleness of these, and the cross motion of the anterior ones, they are very helpless upon the ground, and may be said to crawl rather than to walk. The whole of them are plantigrade, or apply the entire sole of the foot to the ground in walking; and the greater number of them scarcely raise the under part of the body clear of it. They admit of subdivision into two sections, which depend chiefly upon the form of the teeth. The one section have a slight approximation to the rodentia, only they have still the three kinds of teeth which belong to the whole of the carnassiers. Their two front incisors are their largest teeth; but these are conical and pointed, instead of being chisels, like the front teeth of the true rodentia. The other section have long canines, and very short incisive teeth; but after all, except in the most powerful teeth being at the very front of the mouth in the one section, and a little farther back in the other, there is very little difference of character between them. The hedgehogs, the shrews, the musk rats, the golden mole of Southern Africa, and a few others, belong to this section. The moles, properly so called, the star-nosed mole, and the water shrew of Canada, belong to the section with short incisors and long canines. The whole are very obscure animals in their habits; and though they lead very laborious lives they are well adapted for their labour. It is probable that of these, and of all the other small ground mammalia, which live in obscurity, and seek their prey either during the night, or altogether under ground, there are many species besides those which are at present known to naturalists.

CARNIVORA.—These animals form the third and most characteristic family of the order, though there is considerable diversity in their forms and their modes of life. There is a progress traceable to

them all the way from the quadrumana, though the habits of the animal are so very different. The quadrumana, and also the cheiroptera, have perfect clavicles, and the teats of the females are situated on the breast. The insectivora have also perfect clavicles; but as pectoral teats would be inconsistent with their action upon the ground the females have these organs situated on the belly. In the family of the carnivora there are rudimental clavicles; but none of them have perfect ones, and they also have the teats on the belly; and their hind feet bear in general a greater resemblance to their fore ones, both in form and in strength. Among the carnivora, the mouth, which is the instrument that principally determines the kind of food, is uniform in the number, general structure, and distribution of the teeth, though in the form of the cheek teeth there are differences. The whole family are furnished with four large and strong canine teeth, which stand high above the others; and between these there are six front teeth in each jaw, the second one below having its root or fang deeper in the jaw than the others. The cheek teeth never have those sharp points which characterise insectivorous teeth; but some have them furnished with flat bruising tubercles, as well as sharp cutting edges.

It is of some consequence to attend to the distinctions of those cheek teeth, because the variations in their form indicate very correctly the differences of dispositions in the animals. Those next the canines are not the largest, but they are furnished with the sharpest cutting edges. It must be understood, however, that their edges are not chisels for simply dividing, but angularly pointed for tearing, or rather, in this part of the mouth for cutting asunder the flesh on which the animals feed. These are called "false molars," that is, false grinders; but the name is not very descriptive of them, or indeed of any teeth in the mouth of any of the carnassiers; for, as the jaws of their mouths have no lateral play, the one upon the other, there can of course be no grinding action in any part of the mouth. Grinding is an operation required for reducing vegetable matter to a pulp; but animal matter is pulpy enough without any such reduction, and all that it wants is catching and tearing.

Immediately behind these false molars there is, on both sides of each jaw, a tooth, much larger than either of them, and furnished with a tuberculous heel on the inside, more or less perfect in the different species. This tooth is usually called the great carnivorous tooth; and as it has the same kind of trenchant edge on the outside as the false molars, and the heel on the inside, it cuts and bruises at one and the same time. There is a very beautiful adaptation in the form of this tooth. It is the first which begins to prepare the food for the stomach; and as the bruising part is on the inside, it bruises the part cut off, and leaves that which is not cut, with the blood and other juices entire, so that there is no loss or waste in the food of the animal. The remaining teeth behind the great carnivorous ones, are the molars properly so called; but even these are trenchant in proportion as the owner subsists upon living prey. If any of them have the crowns more abundant in tubercles, they are placed farthest backward in the jaw, and they can crush vegetable matter. The dog, for instance, as a less decidedly carnivorous animal, has more of those tuberculous teeth than the cat; and the consequence

is, that the dog can much more easily reduce vegetable matter to a state fit for the stomach, though, if that matter is very hard, even the dog has more trouble in managing it. One of the hardest kinds of ordinary vegetable food with which we are acquainted (if we except the black *raggy* bread of the poor Hindoos, which has to be steeped for some time in water before they can eat it,) is a coarse ship biscuit. If a piece of this is given to a hungry dog (and a hungry dog will snap at any thing), it is not uninteresting to observe the mode in which he goes to work with it, so as to obtain, by his superior means of resource, a compensation for the want of lateral or grinding motion in the jaws. If he gets the whole biscuit, he can readily break it by the snap of the canines, and also reduce it to smaller pieces, by means of the great carnivorous teeth; but when it gets farther backward in the jaws his labour is more difficult; and as he opens his mouth for every attack upon it, he twists the plane of the mouth a little either to the one side or the other, so that the action of the teeth may come upon a new portion. In doing this, he usually keeps the fore part of the jaws higher than the back part, in order that the biscuit may not slide into that part of his mouth which could not act in grinding it, and which, from being farther from the centre of motion, is less powerful in crushing, though more so in biting with a snap, in consequence of the greater velocity which the larger lever gives to it.

If a piece of the same kind of food is given to a hungry cat (and hungry cats will also attempt to eat many substances), the chewing part of the process is far more difficult; and even a common crust of bread is eaten with much apparent labour and not a little grimace.

The different lengths of the jaws, and consequently of the head from the eyes forward in the different genera of carnivorous animals, are well worthy of notice. If the jaws are short, the dead bite, as we may call it, or that which keeps its hold and tears, is, of course, most powerful, because of the shortness of the lever; but when the jaws are long, the snapping bite is by far the most effective, in consequence of the greater velocity afforded by the long lever. In proportion, therefore, as the jaws are shortened, we get dead strength for continued action; and in proportion as they are lengthened, we get quick motion for momentary action. The first of these have more the character of a feeding mouth, and the last blends with this the character of a killing one. Upon the principle to which we have so often alluded, of a divided function in any organ being weaker in each of the parts, than a single function in an organ of equal power upon the whole, it follows that the mouth of the short-jawed carnivora is more completely adapted for eating flesh than that of the long-jawed ones; but that, notwithstanding the large canines with which the more powerful ones are furnished, it is not so well adapted for killing prey—that is to say, it cannot kill prey so quickly. We find in the different genera, that the character of the teeth always agrees with this character of the jaws. If the jaws are short, the tuberculous teeth are fewer in number, and their tubercles less developed; and where the jaws are long, the number of these teeth is greater, and the tubercles more perfect. Even in those varieties of the same species, which must be supposed to have arisen from accidental causes—that is, from causes external of the animals themselves—there is an approximation to the

same character. The long-nosed dogs, snap and very generally seize upon a part where the single bite is effective; as, for instance, a greyhound dislocates the spine of a hare, and a fox cuts the blood-vessel of a sheep's neck; while a bull-dog lays hold wherever he can, and tears away. The smaller carnivora which are long-nosed, and at the same time very sanguinary—such, for instance, as the marten or weasel tribe—generally, if not invariably, seize upon the blood-vessels, or the vertebræ of the neck of their prey, according as the one or the other is more vulnerable; and like expert butchers, they kill and in general suck the blood before they divide the carcases of their victims. Whether professional butchers of the human race at first took their lessons from these animals it is not worth our while to inquire; but it is not a little curious that both should proceed in nearly the same fashion. It is also worthy of attention, that poultry killed by weasels keep longer fresh than those that are killed by animals which have a short bite.

The gradation in blood-thirstiness which we can trace among these animals, as according with their organic structure, is worthy of notice, as showing to what exquisitely nice shades animals are formed for their work. The dog and cat tribes are the most familiar, and also the best illustrations of this. The cats are decidedly the more carnivorous of the two; and therefore they have the mouth more exclusively a feeding apparatus. To compensate for that part of the mouth in which they fall short of the dog, the clutching claws are given them; and the two jointly are more than a match for the dog's mouth in animal murder. But the dog also has his compensation for this deficiency in the mere work of death: the whole energy of his feet is reserved for locomotion; and thus he can chase his prey; and taking him altogether, he is certainly not inferior in proportion to his strength; and indeed, when we take his superior sagacity into consideration, we are constrained to admit that he is the nobler animal of the two—meaning thereby that the effect which he can produce is greater in proportion to the quantity of matter contained in his body.

We have gone somewhat at large into those general characters of the carnivora for a very obvious reason—namely, the place which they hold in wild nature. When we view nature in this way, we must put man, whether savage or civilised, and his accommodations, altogether out of the question. This is the proper way of viewing the subject; for man is really, as we may say, supplemental to the animal kingdom, in character as well as in the epoch of his creation. The possession of the intellectual spirit takes him completely out of the class with the rest; if we neglect to do this, our view of the irrational mammalia cannot fail in being a very distorted one. In this view the carnivora have the highest function to perform,—they are the regulators of the other mammalia, which again are the regulators of the invertebrated tribes, and jointly with these of the vegetable kingdom. The common application of “King of the beasts,” which has often been given to the lion, is not, therefore, a mere fancy, and an unfounded fancy, as some have pretended to assert, who, whether they were aware of it or not, obviously, but more erroneously, have taken man for their type of animal perfection. If we suppose man banished from the world, and the present race of animals left, the lion would be “every inch a king.” It must not be sup-

posed that because the lion rarely, if ever, attacks the full-grown elephant, and still more rarely the rhinoceros or hippopotamus, that this is any invasion of his kingship. Those gigantic animals seem, as we have said, to be the remains of a former race,—the Titans, the Anakims, the giants, of the animal world in the olden time; and from all that now remains, as well as from all that the record of the earth tells us, this appears to have been the golden age of the herbivorous mammalia; for coeval with what seemed to be the first extinct of the new fossil races, there does not appear to have been a single beast of prey.

The family of the carnivora is very conveniently divided into three tribes, two of the terrestrial, and one inhabiting the waters. Cuvier has named them, *Plantigrada*, or walkers on the entire sole of the foot; *Digitigrada*, or walkers on the toes only; and *Amphibia*, or dwellers both in the water and on the land, though the former is the locality in which they find the chief part of their subsistence.

Plantigrada. We have already mentioned that the distinguishing character of this tribe is marching on the flat feet, or applying the entire length of the tarsus to the ground. By this means they have a joint less in action while they walk, than those which walk on the toes. This makes them appear shorter in the legs than they really are, and also slower walkers; so that there are very few of them that can follow prey which walks on the point of the foot, or seize it in the chase. They have, however, some counterbalancing advantages: the flat foot enables them to walk more steadily, and also upon surfaces which would not bear an animal that walks on the toes. They can also stand up on their hind feet, and use their fore ones in seizing their prey; and in some of them, as in the bears for instance, there is so much motion in the wrist joint, that the fore paw acts something in the manner of a clumsy hand, though there is no opposed thumb, and the joints of the toes do not bend so far as to enable them to take hold of a slender object by acting against the heel of the tarsus. Such as have the paw formed in this manner are not inexpert climbers, and they can climb indiscriminately upon trees and the asperities of rocks. The greater number, though not the whole, are nocturnal animals; and in cold countries they pass the winter in a dormant state. The whole of the race have five toes on each of the feet; they are, generally speaking, ground animals, living in darkness and obscurity, and resembling the insectivora in many of their habits, and partially in their form; but they are more powerful animals, and sanguinary in their habits.

Bears, racoons, coatis, badgers, gluttons, and a few other genera, belong to this tribe. In general they have a thick covering of fur to protect them from the cool air of the night, or from the keen atmosphere of those regions which the most powerful of them inhabit. They may be said to be polar animals, or rather to have the locality most favourable for their development in cold regions, though there are a few in warm countries. Their teeth vary in the different species; some, as the bears, have the cheek teeth all tuberculous, and the carnivorous teeth small; while others have the carnivorous teeth and the false molars much better developed. The bears, which have the mouth of the former of these structures, may be considered as the least carnivorous of the tribe; and the gluttons, which have it of the latter, as the most carnivorous. The whole tribe are ani-

mals of unpleasant appearance; and their flesh is, generally speaking, rank and unwholesome; but the covering, of the polar ones especially, is valuable on account of the strength of the skin, and the length and closeness of the fur.

Digitigrada. These are the proper beasts of prey of the land; and the greater number of them capture their prey in a more bold and daring manner. In a state of nature, few or none of them subsist upon any thing but animal food. They do not, however, invariably kill what they eat, for not a few of them feed readily on carrion although it is in a putrid state, whilst some dig in the earth for animal substances which are buried there. Such as feed on carrion have a keener sense of smell than such as do not.

This tribe therefore perform a double operation in nature—that of regulating the numbers of the more peaceable mammalia, and that of clearing the earth of offensive substances; just as the plantigrade carnivora perform a double function in eating animal and vegetable substances. Some have only one tuberculous tooth behind the carnivorous one, and others have two; and there are others again in which the carnivorous tooth in the upper jaw is very small, and that in the under jaw entirely wanting. The last are the most carnivorous of the whole, but the first are scarcely less so; and though they are not furnished with retractile or clutching claws, they can give chase to their prey, by a peculiar sort of leaping march, in the performance of which they are greatly assisted by the length and elasticity of the spine.

The species, and also the individuals of many of them, are very numerous; and in one or other of their genera, they are distributed through all parts of the world; but the greater number of them, though not the whole, disappear before the progress of cultivation, faster than they are actually hunted down by man.

Strictly speaking they consist of several sections, each of which admits of sub-division into genera. The chief of these sections are martens, which are exceedingly numerous in some countries, dogs, civets, hyænas, and cats. In their present geographical distribution, they inhabit from the polar to the equatorial regions, nearly in the order in which we have mentioned the sections, though there are some of each section found in almost every latitude. The martens are most numerous in the cold countries of the north; and though the skins of other animals are valued as furs, the martens are the fur animals properly so called. The native locality of the dog is not known; for it should seem that man has taken possession of the whole race. The fox, which is a sub-genus of the dog, is, however, found from the extreme north to the warm latitudes. The civets and the allied genera are inhabitants of warm countries. This is also the case with the hyænas, but the cats are distributed into all latitudes. The particulars of the different sections or genera of these animals are detailed so fully under their respective names in the alphabetical order, that it is unnecessary to add any more respecting them in this general sketch.

Amphibia. It is necessary to bear in mind that the amphibia of Cuvier's system are different from those of the earlier naturalists, and also that the common notion of an amphibious animal, that of its living with equal ease on land or in the water, does not, in the sense in which it is very apt to be taken, apply to any mammalia, or indeed to any animal whatsoever, in any

one stage of its being; and as the mammalia pass through only one stage, they cannot be aquatic at one time and terrestrial at another. By *living* on land or in the water, must be understood as being capable of breathing the free air, or air through the medium of water; for as no animal can exist without breathing, no animal can be said to live where it cannot breathe.

The amphibia, though they have their teeth formed according to the general type of the carnivora, can hardly be called carnivorous animals. They are rather piscivorous, for they feed upon fish, not upon the flesh of warm-blooded animals; and though the muscles of all animals are considered as flesh in a natural history point of view, yet, in ordinary language, a very wide distinction is made between flesh and fish.

Still, besides having the same general form of teeth, those amphibia have the general structure of body, and many of them all the sagacity of the land carnivora; though the element in which they find their food requires that their organs of motion, and also the general forms of their bodies, should be different. When an animal, starting from the solid ground in its progressive motion, has to make way only against the resistance of the air, the shape of its body does not require much adaptation to the overcoming of that resistance; and as the resistance is small, much adaptation to it would be thrown away. If indeed the animal is to get through the air with great rapidity, then there is a slight adaptation; but estimating from about the average of animal motion, there may be said to be none. It is very different in the case of water; and, therefore, when mammalia are sent to seek their food in the waters, the general shapes of their bodies must be adapted to that element. This is effected by an approximation to the typical form of a fish. The feet are short, much enveloped in the skin, webbed between the toes; and the posterior ones are united with the tail. Their bodies are long in proportion to the diameter; and the spine is capable of very varied and powerful motion; so that besides their fore paws, and their compound posterior extremity, the amphibia may be said to swim with the whole body.

They do not resort to the sea, or other water, merely for the purpose of catching their prey, and come on shore to eat it, as is done by the otters, which, though web-footed, are digitigrade. They eat it in the sea; but they frequent the shores, and are partial to basking in the sun. They are indeed coast animals, and seldom found at any very great distance from land. They belong chiefly to the temperate and the cold regions, in the latter of which they are exceedingly numerous. They consist of only two genera: seals, which are by far the most numerous, both in species and in individuals; and morses, which are remarkable for the vast enlargement of the canine teeth in the upper jaw. They also want both the canines and the incisive teeth in the under jaw. It does not appear in what particular way the morse uses its immense canines, which are directed downwards from a very thick and square muzzle; but it has been supposed that it uses them partly in climbing the rocks of those wild shores which it inhabits, and partly in gathering sea-weed.

In many of the popular books, and also in the older systematic ones, this tribe of the carnivora has been confounded with some of the cetacea. The difference, however, is complete and obvious both in the exter-

nal appearance of the animals and in their skeletons; and those cetacea which have been confounded with the amphibia or vegetable feeders, are chiefly inhabitants of rivers.

It was the old hypothesis that, in these amphibia, the *foramen ovale*, or internal opening from the one cavity of the heart to the other, remained open through life; and from this it was concluded, that if, in man, or in any other land animal, this passage could be kept open, they could remain as long under water as a seal or a morse. The foundation is, however, physiologically incorrect, and consequently the structure cannot stand. The passage of the blood through the heart, without going to the lungs, would not only be of no use, but it would be fatal to any of the mammalia. After the blood has once circulated through the system and is returned to the heart, it is quite unfit for stimulating the systematic ventricle of that organ, or of supplying the waste of life, until it has undergone the action of the air and respiration. Those animals, therefore, do not, any more than the land mammalia, carry on their circulation through the heart while they are under water, they can merely remain a considerable time below; and in this respect the otters make an approximation to them, and they have also valves for closing the nostrils, though less perfect than the valves of the amphibia.

We shall here venture to make a slight departure from Cuvier's arrangement, and instead of considering the marsupial animals as the fourth order in the arrangement, we shall place them as the last. This seems their proper station, if we are to make the arrangement as useful as possible by making it structural, because these animals have a distinguishing character, in an additional membrane and its supporting bones, which does not belong to any of the rest. Farther than this, the marsupial animals do not form one order according to any of the characters upon which the other orders are established; and therefore it really would appear that these curious animals ought to be made a supplement, or sub-class, to follow the true mammalia. We merely mention this, however, without recommending it to be adopted, for we are not making a system, but performing the humbler duty of attempting to explain one.

RODENTIA. The animals of this order are, generally speaking, of small size, but they are exceedingly numerous, found in one species or other in every part of the world except New Holland, and sometimes in numbers so great as at certain seasons to destroy the whole vegetation. Some of the class are the most gentle of the mammalia, and some are so ferocious that, if their size and strength were in proportion, they would be exceedingly formidable. Some of the most curious in their habits also belong to this class, of which we may mention the beaver that builds houses, and there are also many which treasure up stores of provisions. Generally speaking they are more fertile than any other of the mammalia, as the period of their gestation is shorter, and their litters more numerous.

But though the animals differ greatly from each other in size, in external appearance, and in habits, the order is still a very natural one, and true to the character upon which it is founded, which character is well expressed in the name.

Rodentia, formed from the verb *rodo*, to gnaw, means gnawing animals; and this is the action of the anterior part of the mouth in the whale. The typical number

is two large and strong incisive teeth in the front of each jaw, those in the lower jaw sloping forward, and the lip often cleft and the nose shortened in order to be out of the way of those in the upper jaw. The other teeth are generally three grinders in each side of both jaws; but some of the genera have three additional ones which have sometimes been called canines, though they have nothing of the true canine character about them. None of the teeth except the front ones are capable of dividing the food, though they are very efficient in bruising it. The incisive teeth must therefore be considered as the instruments with which the food is taken, though in some species the fore-paws come in to assist. The effective part of the mouth therefore resembles a pair of pincers; and the muzzle is in most of the species rather short, and the head enlarged on the sides for better insertion of the muscles, so that the jaws may gnaw with great force, and also for a considerable length of time. In the individual structure of the teeth there is something curious, as showing how well an efficient cutting instrument among animals agrees with an instrument of the same kind as constructed by man. Man, the handed animals, and the carnassiers of all kinds, have the teeth, in the exposed part, covered wholly with enamel; and animals which grind vegetable substances with their cheek teeth, have the crowns made up of alternate portions of enamel and bone, the last of which wears down a little, and leaves ridges of the other something resembling those of a millstone. The gnawing teeth of the rodentia are different from both of these. They have the enamel placed on their external faces, with a support of bone behind it, which preserves a cutting edge of the enamel, and furnishes a support of a substance which, though not so hard, is tougher; and thus the greatest strength and efficacy jointly are given to those long teeth—teeth which have perhaps more severe labour to perform in proportion to their number than those of any other animal. This is exactly the plan to which a workman has recourse when he wishes to make a tool which shall retain the keenest and most durable edge, and which yet shall have sufficient toughness not to snap by a pretty severe cross strain. A thin piece of that description of steel which becomes hardest by tempering, is applied and fastened to the side of a thicker piece of iron. Then that which is to be the cutting edge is chamfered off on the face which has the iron to form basil; and thus while there is steel enough for all the purposes of cutting, the iron supports it up to the very edge, so that the tool can cut finely, and yet bear pretty rough usage. There is another advantage to a tool of this kind: it is more easily sharpened than if the whole of it were formed of even softer steel, because the iron is ground down much more easily than steel would be. This application of the two substances in the teeth, has the same advantage in the sharpening of them, or rather it keeps them sharp by the very fact of using them; for though the enamel does wear, the soft bone behind it has a tendency to wear faster, and by this means the edge of the tooth never gets blunt, let the animal gnaw as it will. There is also a provision against the wearing down of the teeth in their continuing to gnaw during the whole life of the animal, which is not the case with teeth that are entirely cased with enamel. The fact has not been absolutely decided, but we have reason to believe that the growth

of the tooth is in proportion to its wearing, and consequently to the use that is made of it. This, however, is not absolute; because if one of the teeth in either jaw is lost, the corresponding one in the other jaw grows so long that the animal can use the mouth with difficulty. There is another circumstance which assists in this operation, and that is the form of the condyles by which the lower jaw is articulated. These are elongated from front to rear; and thus, though they admit the point of the under jaw to be advanced or drawn back as the operation of gnawing may require, they do not admit of any lateral motion. This gives great firmness to the bite of these animals; and thus, though their teeth are not calculated for inflicting punctured wounds as the canine teeth of animals are, they can bite out a piece equal to their extent much more quickly than any of the teeth which are formed for eating flesh. The cheek teeth have flat crowns with transverse ridges of enamel, and the interstices filled up with bone. These ridges in the opposite jaws nearly fit into each other, so that the grinders can act something after the fashion of the hand instrument which was used for breaking the "boon" of lint before the more expeditious and successful expedient of rollers was resorted to. The crowns of the cheek teeth are not, however, exactly of the same form in all the rodentia. If these crowns are perfectly flat, with only the exception of the transverse ridges of enamel, the owners live exclusively upon vegetable substances. If the ridges are divided into smooth tubercles, the owners are more miscellaneous in their feeding, and eat indiscriminately a variety of substances; and if the tubercles are drawn up into sharp points, their owners possess a little of the disposition and habits of the carnassiers.

The extremities of the rodentia are seldom of equal length, the hind legs being longer than the fore ones in most of the species. In proportion as these are longer, the muscular substance and power of the animal is more concentrated upon them. Their motion is, generally speaking, leaping and not walking, even when it is slow: and those which have the hind legs very long can leap to great distances compared with the size of the animals.

Though exclusive vegetable feeders in many of the genera, the rodentia have only a single stomach; but this deficiency is often made up by a cæcum of very large size. The dormice, however, have not this appendage.

The brain, in all the order, is but little marked with convolutions on its surface; and as those convolutions are popularly supposed to be some way or other connected with sagacity and resources in proportion to their development, it is customary to say that persons who have little sagacity or resource, and are giddy and wavering, are hare-brained. The eyes are placed laterally, and the form of the zygomatic or yoke arches shows that the jaws are but weak. Strength in the jaws is not the requisite, it is rather lightness, because the action is continued gnawing or nibbling, and not powerful biting. This may be seen in the different ways in which a monkey and a squirrel go about to get at the kernel of a nut. The monkey takes it between his strong jaws and cracks it at once by one lusty gripe; while the squirrel nibbles away till it makes a hole in the nut. As the fore arms have but little motion in the elbow joints, and their two bones are often united, the paw cannot turn, but has merely a hinge motion in this particular

joint. Many of them, however, have tolerably perfect clavicles, and others have imperfect ones, so that they can bring the paw to the mouth without any turning of the elbow; but as they cannot turn up the sole of the paw, they cannot bring any substance to the mouth except by holding between the two paws sideways.

In all their organisation, indeed, they are inferior to the three preceding orders; and the offices which they perform in nature are of a more humble character. Those which subsist on vegetable matter live, habitually in some cases, and seasonally in almost all cases, upon bark and twigs, and even dry sticks; and it is not a little remarkable that the beaver of the north, notwithstanding all his ingenuity in hut building, should be contented with nearly the same fare as the hippopotamus of the African rivers, which kennels in the foulest ooze that it can find. In proportion as the clavicles are firmer, the animals have more dexterity in their action; and this admits of a division of them into two sexes, which is rather convenient in the case of animals which are so very numerous, and the greater number of which, from their habits of concealment, are but little known.

The section with clavicles is by far the more numerous of the two, and contains a number of families, some of which, however, do not consist of more than a single genus, or even a single species. The first family, and those which are the most agile animals, are the squirrels, including squirrels properly so called, leaping squirrels with extended parachutes, usually called flying squirrels, the eye-aye, and perhaps a few others. They are almost exclusively tree animals, and exceedingly quick in their motions. The second family consists of the rats, of which there are thirteen or fourteen separate genera, some inhabiting the mountains, some the walls of houses, some the fields, some the margins of the waters, and, in short, almost all sorts of places that can well be imagined. They are the most numerous mammalia on the face of the earth. All of them, however, are ground animals, and some of them inhabit vast colonies together. Their numbers show that they are of vast use in wild nature; and though most of them which frequent houses are accounted pests, yet as they multiply very fast in such situations, we must not suppose that even there they are altogether without their use. The jumping hares, the rat moles, the beavers, and various other genera, the species of which are but few, and the manners imperfectly known, also belong to the selection with clavicles.

The section without clavicles contains only three families; but some of them are animals of considerable interest. One family consists of the porcupine and the allied genera. Another consists of the hares; and the third of the cavy, including among others the chinchillas of the South American plains, the skins of which are so much esteemed for the beauty of their fur.

Several of the rodent animals are offensive, on account of their musky smell; but the flesh of the greater number is eatable, and that of many is highly prized. The skins of many besides the chinchilla are also valuable, on account of their furs, though less so than those of the marten family, inasmuch as the skin and fur are more tender, and the fur is less glossy. The vast numbers in which many of them are obtained, and the comparative easiness of the hunting of them, make some compensation in those respects.

EDENTATA. As the character from which this small but very singular order of the mammalia gets its name is merely a negative character, the absence of certain parts, and not the possession of them, no conclusion respecting them can be founded upon it, farther than that they are incapable of inflicting an incisive bite with the front part of their mouths. Still they have some characters in common, although those characters differ very much in the several genera which the order comprises. Those characters are the peculiar structure of the claws with which the extremities of the toes are armed, and the degree of motion. Generally speaking the claws are large, and in order to fit them for more powerful action, they embrace the terminal bones of the toes like a sort of very singularly shaped hoofs. This is the character in which they agree; and those in which they disagree are chiefly the size and form, which vary according to the purposes to which the animals most habitually apply them. There are three of those purposes: holding on upon trees, digging in the ground for the simple purpose of burrowing, or for digging up bulbous roots and earth insects, and also for digging into the bodies of dead animals, into which they enter by making a mine below. The third form is that which is more adapted for tearing open the burrows or collections of earth, chips of wood, or other materials of which those insects that live together in numerous colonies construct their habitations. The first and last of these three varieties of claws among those animals, will be found explained, both in their structure and their action, and also illustrated by sketches in the passages already given as explanatory of the feet of sloths and ant-eaters. An example of the third form occurs in the ground hog of Southern Africa, of which a figure will also be found in the course of this article. The whole order are local in their distribution, as well as peculiar in their structure and their habits. Very few of them, and these only of one of the genera, occur in temperate countries, and such as do are confined to America. Cuvier divides them into three families: *Tardigrada*, containing only the sloths of living animals, and, according to Cuvier's hypothesis, the megatherium, and those other fossil animals which are presumed to have resembled it in structure; *Ordinary Edentata*, containing the armadillos and a few others, all of which are exceedingly expert at burrowing in the ground; and *Monotremata*, comprising the ornithorhynchus and echidna of New Holland, the one of which is a burrowing animal, and the other aquatic in its habits, and seldom coming to the surface excepting in order to breathe. These two are very peculiar animals. There is no question that both of them are mammalia, and there is as little question that they resemble the ordinary edentata in having no teeth, and also in some parts of their internal organisation; but still their peculiar character, that of having only one posterior opening to the body, is the one in which they differ from all the other known mammalia; and therefore it seems desirable that they should stand apart and be classified upon it. Enough of their physiology and manners is not yet known for enabling us to fix their place in the system with any thing like precision; and therefore we shall venture to arrange them as unclassified animals in supplement to the marsupial ones, because they too require to be classed upon different principles from the mammalia.

PACHYDERMATA.—This is also an order which is

established upon a character which tells us but little ; and the three families of which it consist differ much from each other. They are all vegetable feeders ; and as such they form a pretty distinct division. Their digestive apparatus is invariably of large dimensions, but they do not ruminate ; and as many of them at least are capable of dividing their food but imperfectly with the teeth, they may be said to draw a tincture from it rather than to digest it in the usual meaning of that word. None of them are furnished with claws ; and the termination of the foot differs considerably. Some have short blunt toes, as for example, the elephant ; others have divided toes with little hoofs, as for instance the tapir, and some have one large divided hoof, as the horse ; in fact, there is no part of their external organisation in which they can be said to have very much resemblance ; and the thick skin upon which Cuvier has judged it most expedient to class them, though it is very characteristic in some, is much less so in that of others. The elephant, the rhinoceros, the hog, and several others, have undoubtedly thicker skins than are to be met with in any other order of mammalia ; but the skin of the horse is certainly not thicker than that of the buffalo. The three families are, *proboscidea*, ordinary pachydermata, and *solidungula*. The first of these contains only the two species of elephants, of which some notice has already been taken ; and the last contain only the horse genus in its different species. Both of these are very distinct in their characters ; and they are animals of peculiar interest ; but they stand alone in the system, possessing little or nothing of what is called affinity to any of the rest. The second family, like that of the ordinary toothless animals, is a melange, containing animals very unlike each other, such as the hippopotamus, the different hogs, the rhinoceros, the tapir, and various extinct animals of which of course only the bones are known, and all the rest must be supplied by analogy, which, however, is a powerful instrument in the hands of one who has carefully studied the skeletons of all the living animals, and compared these with their external appearances and their habits. With the exception of the hog, and the horse, of which the original locality is not very well known, all the living genera of these animals are comparatively local, and found only in the southern parts of the true continents. The bones of the extinct ones, however, are perhaps more widely distributed than those of any other mammalia which are lost to the world in living types. Among the ordinary ones there are some, as, for instance, the tapir, which in some respects at least resemble the elephant ; and in the hogs we have a divided hoof resembling, though not exactly like, that of the ruminating animals.

RUMINANTIA. This is to man the most valuable order of all the mammalia ; and it has the advantage of being very abundant, almost universally distributed (Australia always excepted), generally speaking mild in disposition with very few exceptions, social in habits, and consequently easily tamed.

The character upon which the order is established is a very distinct one, belonging to the whole of the order, and to no other mammalia. In some others there is a stomach more or less dissected, but these do not ruminate. Ruminating animals are also the only ones which are provided with horns inserted in the bone at the upper part of the head ; for the

horn of the rhinoceros is merely a great tuft of hair, or bristles very firmly soldered together, and attached only to the skin. All the ruminating animals are not, however, furnished with horns ; and therefore, when in a state of nature, the horned and the hornless are good distinctions. In domestication, however, the case is different ; because some animals which are naturally horned lose them in domestication. We believe, however, that there is not a single instance of the converse, namely, of a hornless animal acquiring horns in a domestic state, how long so ever it may be breeding them. Indeed we do not think there is a single instance in which a domestic animal acquires a single appendage, though there are many in which appendages are nearly or wholly obliterated. It should thus seem that, while domestication unquestionably softens the manners of animals, it also smooths the asperities of their forms. This fact involves some curious matter for the physiologist, though it hardly comes within the pale of legitimate natural history. We may remark, however, that all animals, when under the influence of strong and angry passion, become much more rugged than when they are pleased. The hair stands up, the muscles swell into ridges, the skin is puckered, and the animal puts on an aspect as repulsive as possible.

As ruminating, or returning the food to be chewed after it has been in the first and second stomachs, is the leading character of this most valuable order of animals, we shall say a few words on their system of nourishment generally. In some other mammalia there is a partial division of the stomach into compartments, in each of which a different function is performed ; but in the ruminantia there are four distinct and separate stomachs, each of which performs its separate function, in assimilating the food of the animal. The first is the paunch, which can be viewed in no other light than that of a mere receptacle. It is very capacious, and fitted for receiving a large quantity of the grass or other matter upon which the animal feeds ; but there is no gastric juice, or any other solvent fluid which enters it ; and thus it is simply a receptacle. In some cases it is extended with great inconvenience to the animal, in consequence of the fermentation of its contents. This is especially the case when cattle eat clover which has been moistened by rain or dew. This moisture, unnatural to the state of the animal, causes the production of a great quantity of gas, carbonic acid generally speaking ; and the quantity is so great, in some instances, that it would burst the animal if allowed to remain in the stomach. To prevent this, the skilful grazier, knowing the exact point at which the animal is safe, plunges a knife into the body of the animal, so as to enter the paunch without injuring any of the other viscera, or even dividing any blood-vessel of consequence ; and when this is done the gas issues from the wound with force and violence similar to the blowing of a pair of bellows, and the animal is instantly relieved, and its functions go on as if nothing had happened. This first stomach can be regarded only as a simple receiver, but a very conspicuous one ; and the ruminating animal is enabled to browse for a long time and fill the receptacle, before the proper operation of preparing the food for the stomach begins.

The food which is taken into the paunch must undergo another operation before it is even ready for the digestive organs ; that is, it must return to the

mouth in order to be chewed, or ground by the lateral motion of the cheek teeth upon each other. It is this returning of the food to the mouth after it has been in the paunch, which is called "chewing the cud;" and the cud, or *quid*, which is the real meaning of the term, is not unworthy of notice, inasmuch as there is a separate organ for the preparation of it. This organ is the second stomach of the animal. It is called the bonnet, or the king's hood; and it is a viscus of a very peculiar structure. It is very muscular in its walls, and the interior of it consists of cells, which are larger or smaller according to the size of the animal, and the nature of the food upon which it more habitually subsists. The walls of these cells have the faculty of standing erect, at the same time that there is a vermiform, or twisting motion of the entire organ. By means of these cells and of this motion, the food which had been taken into the paunch is rolled into little pellets, which pellets are one by one returned to the mouth and undergo the operation of chewing; and unless this operation can be performed, and the king's hood can properly prepare and return the food to the mouth of the animal, that food can in nowise contribute to its nourishment. From spasm, or other causes, it sometimes happens, that this organ is incapable of performing its function; and when such is the case, the animal will die although still able to graze and convey the requisite quantity of food to the paunch. An intelligent observer of cattle is well aware of this peculiar species of spasm, and he is also aware that there is only one means of getting the better of it. It is a disease which no medicine can reach; and if he possessed only one animal, and that animal were taken with it, it would have no alternative but death. He therefore watches another animal of the same species, and the moment that it is bringing the cud or quid to the mouth, he snatches it out, and transfers it to the mouth of the animal which has lost the quid; and the stimulus of the warm quid so applied, rarely if ever fails in restoring the animal to the complete exercise of its function.

The cells in the second stomach vary considerably in their dimensions in the different orders of ruminating animals. In those which nibble the tender grass, such as the sheep, they are small; but in those which live on the branches of trees, or on coarse vegetation of any kind, they are comparatively large. This is especially the case in the camel, which has the cells of this second stomach of ample dimensions. The size of these cells give origin to the ridiculous story that the camel is capable of retaining in its stomach a supply of water which can not only refresh itself, but which is rendered available as drink to its master as it traverses the burning deserts. This notion has been strangely continued, even by men who in recent times have got honorary names heaped upon them for the supposed services which they have rendered to science. Notwithstanding this, there is no opinion more absurd, or more completely opposed to every principle both of chemical and physiological science; and if it were not that we have a desire to be tender of the names of those whom learned societies tag with letters, and upon whom kings bestow knightly honours, we would say that there are many of them sheer blockheads, who ought to be ejected from the province of science as unworthy usurpers.

After the food has been rolled into pellets by this second stomach, returned to the mouth and properly

chewed, it is carried back again to the third stomach, which is termed the "manifold," because it consists of parallel laminae, bearing some resemblance to the leaves of a book. These are beset all over with small tubercles, and this is the portion of the stomach in which, and in which alone, the drink of the animal mingles with its food. If, therefore, water would be sought in any one portion of the digestive apparatus of a ruminating animal, this is the portion in which alone we could by possibility find it. There is, however, no instance in which water has been met with in this viscus, unless so completely mixed with the aliment as that the one could not be separated from the other.

From this third stomach, the food and the drink combined, and reduced to a pulp upon which the real digestive process can be exercised, are conveyed to the fourth or truly digestive stomach of the animal, which is the only one that secretes gastric juice. This stomach is in some parts of the country known by the name of "the red," and in young animals of the ox tribe it is used for the purpose of coagulating milk in the manufacture of cheese, and gets the name of the "rennet." Such are the principal digestive organs of the ruminating mammalia, and in addition to these their intestinal canal is very long, and provided with an ample cæcum.

It is not a little remarkable that these animals, which are unquestionably the most useful to man of the whole mammalia, should be at the same time most amply provided with the means of digestion. There is another circumstance connected with their economy which is well worthy of attention, and that is the fact that they absolutely make their own pastures. If a heath-clad hill or a barren moor is perseveringly pastured on by cattle or by sheep, it will in time become a green sward of the most kindly description. The droppings of the animals no doubt contribute to this purpose, but there is a kindliness also in the very bite of a ruminant animal which appears to do good to the plant on which it feeds; there is also something peculiar in the breath and the whole economy of these animals, for there is nothing that tends so much to retard the progress of consumption in the human subject as breathing the breath of cattle, and we need hardly mention that the smallpox, formerly one of the most destructive diseases of the human race, has been well nigh banished by the counteraction of inoculating matter originally obtained from the teats of the cow.

Indeed, in whatever light we view the ruminating mammalia, they are absolutely the treasures of man above all other parts of the animal creation. For rapidity and elegance their labours are perhaps not equal to those of the horse, but in patience and strength they have hardly any parallel; and among the poor it is hardly possible to imagine a more valuable treasure than is possessed in a single cow. It is also worthy of remark, that nature appears to have been more bountiful in the distribution of the ruminantia than of mammalia of any other order. It is true that, in the wild plains of South America there were originally no animals of this description, but since they were introduced they have multiplied to an extent unprecedented in any other part of the world. It is also highly probably that they have altered the character of the surface, and that, though still seasonally arid in a high degree, the wide plains of Paraguay and Brazil do not become so burnt up in the dry season as they did

before they became the pastures of such numerous herds of cattle.

The only native ruminantia of the southern part of the American continent are the lamas, which, though much smaller animals, are somewhat allied to the camels. They are, however, fitted for treading on very different ground. The foot of the camel, which is planted with a heavy downward stamp, and lifted straight up and high, is adapted for sand; but it is a very bad foot for rough and stony surfaces. Though the lama inhabits latitudes in America which correspond very nearly with those inhabited by the camel in the eastern continent, the feet of the lama are adapted for surfaces of a very different description from those trodden upon by the camels. The camel is an animal of the sandy plain, but the lama is a mountaineer; and the different species are found along the ridges of the Andes, largest we believe in the equatorial parts, but more numerous and more active farther to the south, where the pastures are better. Instead of the two toes in the lama being united on the under part, and forming one entire padded foot as they do in the camel, they are well separated, and each is furnished with a complete pad, as may be seen in the following cut.

The foot is remarkably well adapted for holding on upon the rough surfaces of rocks and precipices; and thus though the lama is but a small animal, not larger or stronger than a common deer, it is very sure-footed on mountain paths; and before the introduction of the mule, which is now the beast of burden chiefly employed in those countries, it was much esteemed by the native Peruvians.

Although the characteristic foot of the ruminantia be in all cases a divided one, consisting of two principal hoofs upon which the animal treads in walking, without the small supplemental ones coming to the ground, except where that is soft, and the animal sinks deep, yet there is still a very remarkable adaptation in this simple foot to the places which the animal inhabits. The larger buffaloes which inhabit marshy places, and, generally speaking, the whole of the ox tribe, which prefer humid surfaces to dry and elevated ones, have the hoofs very broad, so as to present an extended base to the soft ground. This form of foot gradually changes as we proceed from humid pastures to those which are dry and elevated; and when at last we come to the goats and antelopes which inhabit the craggy steepes of lofty mountains, we find the hoofs very small, hard in their texture, and firm in their edges. In proportion too as the foot acquires this mountain character, there is a corresponding increase of elasticity, not in the leg merely but in the whole frame of the animal; so that while these ruminantia which inhabit the moist plains are

slow and unwieldy in their motions, the mountaineers are among the most light and bounding of all the mammalia; and there are no animals, not possessed of hands, or prehensile feet of some kind or other, which can preserve their balance so well upon such narrow footing. Some of the rock goats and rock antelopes can stand firmly upon a pinnacle of rock hardly more extensive than the human hand, and not only so, but they can bound from this narrow footing with wonderful elasticity, and alight securely upon a fresh one equally narrow.

In mentioning this order of animals, we cannot pass over their extreme utility to man, and the numerous ways in which they are useful. The milk of the ruminant mammalia is much more abundant than that of any of the others, and it is superior in quality, being one of the most healthy substances that is known. The manufacture of this milk into cheese, or that of its cream into butter, employs a great number of people; while the commerce in these articles is an extensive branch of trade. The flesh of the ruminants is a staple article of food in all nations; and though there are some articles which the luxurious esteem more as rarities, there is no kind of animal food upon which a man can feed so constantly and preserve an equal state of health. The skins of these are so valuable as leather, that they form an indispensable article of human clothing, and in many of the arts; and the skins of the different genera, and those of the same genus, at different ages, and in the different sexes, admit of being dressed in a great variety of ways, so that each is applied to its own specific purpose. The wool and hair are also articles of great value; and no part of the dead animal is without its use.

But notwithstanding those numerous and important uses of the substance of the animals, they are nothing to the uses of the animals themselves in a live state. The great quantity of vegetable matter which cattle convert into manure for the fields, and the peculiar adaptation of this to the nourishing of corn and of the more kindly grasses, render these animals indispensable to the farmer; and we may say with truth, that there is not upon the face of the earth a single spot so fertile as that it could bear corn crops even ten years without the assistance of cattle. The beauty of the animals too is something; for if the greatest master of colours limns a landscape with the utmost effort of his art, and forgets cattle, it looks cold and desert; and one would prefer a single cow touched by the broad and brilliant pencil of Cuyp to all the still life in the world. In fact, those animals appear to have been the grand means whereby the human race were at first brought from their savage habits. The naked hunter of the woods, who is understood to have subsisted chiefly upon the flesh of animals, and to have been hardly less ferocious in his manners than the carnivorous mammalia, became in time a shepherd, feeding upon milk, and clothing himself with the skins, and ultimately with the fleeces of his flock, till their great value taught him to love the gentle creatures; and when this step was once taken, the milk of human kindness was poured around the human heart, the attachment of man to the animal kingdom was placed upon a finer and firmer basis than the mere desire of eating their flesh; and the moment that a gratification in supplement to that of the mere animal appetites was afforded, the first grand step in civilisation was taken; nor was it long ere

the descendants of the shepherds founded the city, reared the palace, established the law, cultivated science, improved art, and enjoyed happiness. This is part of what we owe to the ruminant mammalia; the whole tale of their value and advantages is too long to be told.

MARSUPIALIA.—In stating our reasons for removing these animals from the end of the flesh-eating order, we took occasion to remark that they ought, in strict propriety of arrangement, to form a sub-class, or a separate class altogether from the regular mammalia, because the character by which they are all distinguished, and upon which they are named, does not belong to any of the rest. This character is the attachment of a *marsupium*, that is, a purse or pouch on the under part of the females, which pouch is supported by two peculiar bones called marsupial bones for the sake of distinction; and the degree of its development varies in the different genera, and also is the same female when in different states. In some it is always largely produced, and answers as a receptacle to the full-grown young; while in others it is so little produced at any time, that it never covers the teats of the animal. There are, indeed, cases in which the pouch is little more than a ridge or fold upon each side of the belly laterally; but the bone exists to some extent or other, even where the distinct pouch is wanting, and thus the whole of these singular animals are brought into one class; and there would be no objection to consider them as an order, only they do not strictly agree with the other orders of the mammalia, in any great particular either structural or physiological.

The bones which support the marsupium are attached to the pubis, and embedded among the abdominal muscles, so that the pouch is retained in its place with a degree of force proportionate to the strain which it has to bear. We may see in part the use of the singular structure of these females. Their habit requires that they shall be much in a slanting or upright position; and the strength of their muscles being, in the more characteristic species, concentrated upon the loins and haunches, uterine gestation, until the young were well advanced, would neither be convenient nor safe, accordingly there is a different arrangement of parts in them, and instead of there being but one opening to the uterus, as in the proper mammalia, there are two canals of comparatively small diameter, and curved in their direction. There are in the organs of the other sex peculiarities which answer to these; and though the formation is certainly singular as compared with that of the mammalia, the adaptation which it evinces is nowise inferior, only as the habits of the animals are not very well known, and as they were for a long time considered and classed with the others, and their more remarkable peculiarities passed with little notice, the proper study of them may be said to be little more than in its infancy.

There is no doubt, however, that the whole of the animals have a double gestation—a gestation in the pouch, and a gestation previous to that in the internal uterus. It has not been very satisfactorily made out whether the young, when in the uterus, have or have not a regular placenta; but the analogy is against their having one in any considerable state of development; and in those species which have been observed, the young, when they leave the uterus and be transferred to the pouch, are too rudimental for

having an umbilical cord in any state of development. They are far more minute and formless than the young of any of the mammalia, not excepting those which come into the world blind and naked; and in some species at least (for the greater number have not been examined with sufficient care), they are without any produced members, or any decided marks of systematic action of any kind. The female transfers them to the pouch with her mouth, or applies them to the teats in those instances where these are not covered by the pouch. It is upon the nipple or teat, indeed, that the young one is suspended, and not by the mere pouch; and when very rudimental ones are removed from the teat, they cannot regain it without the mother's assistance, and thus they would perish in the pouch without being able to help themselves.

It is of course not known whether all the species are equally rudimental when placed in the pouch, or indeed, whether the same female places all her young ones in it at the same age. This is most probably the case; but the point is one upon which we cannot speak positively, and, indeed, the whole doctrine of the production of these animals, is one which must be worked out upon its own data, without any analogy drawn from the other mammalia. In those species which have been open to accurate observers, the whole period of gestation, at least up to the perfect formation of the young animal, though not of course to its growth, has been found nearly equally divided between the womb and the marsupium; only the young ones take shelter in the latter after they are capable of finding the greater part, if not the whole, of their own food. Where this is the case, the marsupium is of course considerably enlarged; but it is not in this that the principal office of this organ consists. In its internal covering, partially also in its teats, and perhaps wholly in these in some of the species, this part of the system is only temporary and developed when nature requires it, and disappears again when the necessity for it ceases.

The minute description of the curious economy of these animals is not very well adapted for popular illustration; and though it were so adapted, it is too scanty for admitting of being made satisfactory. We may remark, however, that by far the greater number of the marsupial animals are either leapers or climbers; and this peculiar arrangement of the organs of gestation is evidently intended to enable the loins and haunches to have more powerful action in this way than they would have if the animal were loaded with full grown young. The double internal uterus and the marsupium also enable these animals to bring forward a succession of young ones at the same time; and they may be observed in the pouch at evidently different ages in the different individuals which are there at the same time.

All those circumstances point strongly to the fact, that these animals are subjected to considerable hardships and contingencies; and this agrees with the characters of those countries which the greater number of them inhabit. These are chiefly seasonal countries, in which there is much alternate parching and flooding—countries in short which are not well adapted for the common mammalia in a state of nature; and accordingly we find that in New Holland, which may be considered the head-quarters of marsupial animals, there are no native placental mammalia, and such mammalia are not very common in

N

the other localities of these animals. New Holland, New Guinea, some of the other islands of the archipelago, South America, and the warmer part of North America, in the case of a single species only, are the localities of these animals; and it is not a little remarkable that not one of them has been hitherto found in Africa, though they occur on both sides of it.

As they have their portion of the earth set apart for them as it were, they are distributed into their own orders, which, however, have been usually taken into the system as genera, and perhaps it is not worth while to alter an arrangement which cannot be misunderstood, if we do not confound them with the other mammalia.

The singular part of the economy of these animals is, however, the pouch, and the double gestation. There has been much inaccurate writing on this subject, but the leading facts have been in a great measure cleared up. The Virginian opossum, which has been longest known, has been examined with a good deal of attention. From which it appears that the pouch begins to be visibly preparing for the young about the tenth day, and that in about five days more the young are placed in it. This is done always in a state of concealment, and consequently the exact method of it is not known, though there is no doubt the mouth is the instrument. When these young are deposited in the pouch they are very small, not exceeding a grain or two in weight. The mother, it is to be borne in mind, is about the same size as a common domestic cat. On the twenty-fifth day the motion of the young in the pouch is sufficiently great to be felt by the finger on the outside; and by eight or nine weeks the young ones are found hanging, some without and some within the pouch. While they continue suspended to the nipple it is about a quarter of an inch long; but they do not quit the teats till they are about the size of rats. After this the teats begin to shrivel up and soon disappear. About the eighth week the eyes are opened, at which time they begin to quit the teats, though they return to them for some short time.

The marsupial bones, which are found in the skeletons of no other animals, form a very peculiar character. They are inserted by a tendinous union, and not by joints near the middle of the pubis, and directed towards the sides; and it does not appear that there is any necessary correspondence between the development of the bones and that of the pouch in its soft parts. The males have them as well as the females and those which have the pouch but very little produced, have often the bones very decidedly so. Though the pouch and its economy be the most remarkable, they are not the ones upon which it is convenient to divide the animals, the proper mode of division being the teeth and feeding apparatus, as in the case of the mammalia properly so called. But whatever may happen to be the food or teeth of these animals, and whether the pouch is well developed or merely rudimental, there is a family likeness which runs through the whole. The animals never have the graceful form of the true mammalia; they have a very stupid look and expression in comparison to these, and they are sadly inferior to them in resources, though their dispositions are generally mischievous enough in proportion to their strength.

In the marsupial animals, and particularly in those of them which have the marsupial character most

completely developed, there are certain conformations of the blood-vessels in the lower part of the body, in which they differ from the mammalia. These conformations tend to secure, in proportion to the blood of the whole animal, a greater supply of arterial blood to the lower extremities, and to those parts in which the peculiar characters of the animals are situated. The marsupium and its bones render the pelvis deeper than it is in any of the mammalia, and this enables the iliac branches to come off earlier and at smaller angles, by which means the blood circulates more freely and in larger quantity, and this supplies the waste of the more powerful action of the hind legs, and, generally speaking, also of the tail. Those peculiarities cannot be very clearly explained, however, without the assistance of figures, and not easily to ordinary readers with them.

The spine and skull do not differ greatly from those of the common mammalia in the arrangement of their principal parts, only in the more characteristic species, the skull is smaller in proportion, and the vertebral column is enlarged towards its sacral extremity. The fore legs are always furnished with complete clavicles, and thus they have always a cross motion, so that the animal can grasp with them or bring them to the mouth. In their development the organs of sense follow nearly the same law of adaptation to locality as is found in the mammalia; but the fore paw has in no case less than four fingers and a rudimentary thumb. Some of them, however, have the fore feet adapted for digging in the ground; one or two have the toes of all the feet webbed, and several have the hind feet formed like those of the leaping animals. Some of them, as the koala, have the toes of each foot divided into two groups, an external one containing three, and an internal one containing four, which act against each other in grasping. In those which simply run upon the ground, and which are more or less of a carnivorous character, the feet approach more to those of the running carnivora, having five toes on the fore feet and four on the hind, all armed with claws which are sharp and crooked, but not retractile. The whole race are, with but few exceptions, solitary animals, living alone, and rarely found in more than a single pair, and that only occasionally. The kangaroos are almost the only ones which form an exception to this; and they make a slight, though a very slight, approach to the ruminant mammalia in their food, and the fact of their being of some use to man; but the approach is but a slight one, and their social principle is not sufficiently strong for admitting of their being tamed.

We shall now very shortly notice the several genera, or, perhaps, to speak more accurately, orders or sub-orders into which these animals are usually divided. The first are the opossums, which are wholly American animals, though some are furnished with a pouch and others not, and one at least is aquatic in its habits. These animals have their mouths formed very like those of the insectivorous mammalia. They have ten front teeth above and eight below, which last are very small; one canine tooth in each side of both jaws, which is strong and compressed; and seven cheek teeth in each side of both jaws, the ones next the canines very small, and the others with pointed tubercles like all insectivorous teeth. The head is long, the muzzle pointed, the gape wide, the ears rounded and nearly destitute of hair, and the tongue studded with hard points

They walk on the flat foot; have five toes on the feet, only the thumbs on the hind feet have no claws, and are opposable to the fingers. The tail is very long in all the opossums, hairy in part, and naked in the other parts. They are covered with pretty close fur; and like the insectivorous mammalia they have the stomach simple.

They are animals of a rank and offensive smell, residing in holes of trees during the day, and crawling about and climbing during the night, levying their contributions upon little birds and their eggs, as well as upon insects. The Virginian opossum is the largest, and it does not exceed the size of a cat. It is furnished with a pouch; and so are three or four other species inhabiting South America; some of which frequent the rocks by the sea side, and feed upon crustaceæ. Others of the same country, which are not much larger than common rats, are without the pouch; but its place is marked by deep folds along the side of the body. One species of Guyana, which is about the size of a pole cat, has the feet webbed, and its manners are understood to bear some resemblance to those of the otters.

Those which have been enumerated comprise the whole of the American species, so far as these have been discovered. They are, comparatively speaking, as obscure as well as an useless race of animals; though in a country where insects are so exceedingly numerous, every insectivorous animal is of some service.

The marsupial animals of New Holland are much more characteristic than the American ones; and there is a succession of them, answering in a great measure to three or four different orders of the common mammalia. The colonists in Australia have bestowed the names of common English animals upon the greater number of them; and this at first led to mistakes respecting their natural history; but those mistakes have been in a great measure rectified.

The genera of these Australian marsupial animals are, *Dasyurus*, which are carnivorous animals; *Perameles*, which have more the form of badgers, though not very like those animals; *Phalangista*, which are climbing and leaping animals; *Plautista*, which have the skin of the sides formed into a parachute; *Poturus*, which resemble rats; *Kangurus*, of the leading species of which we have already taken notice in speaking of leaping animals; *Phascogale*, which is a small animal, remarkably slow in its motions; and *Phascogale*, which is also a very slow ground animal. It is necessary to bear in mind, however, that those phalangists (*Phalangista*), which have the tail naked or covered with scales, are natives of the islands to the north east of New Holland; while those which have the tails covered with hair are natives of New Holland itself. Some species of these have been set down as American, but it does not appear that there is any truth in their being natives of that country. To these must be added, though in separate sections, the two most singular animals of Australia, or indeed of any part of the world. These are, the ornithorhynchus, which is a swimming animal; and the echidna, which is a burrowing one. There is no doubt that these two follow the general law of the marsupial animals; though a regular pouch would not be consistent with an animal which crawls and dabbles in mud at the bottom of pools, or yet with one which burrows rapidly in the ground.

The fact of these two animals having only one posterior opening to the body, as is the case in birds, together

with their jaws being drawn out into horny mandibles something like those of birds, and like them destitute of true teeth, were strong inducements to the naturalists by whom they were first observed and examined, and who had been in the habit of carrying one type through each class of the vertebrated animals, to look upon them as a kind of birds, or perhaps as partaking of the characters of bird and oviparous reptile, jumbled together with those of the mammalia. Such a melange of character is, however, inconsistent with all that we meet with in the other parts of nature; and though in the mammalia, whether common or marsupial, there are very remarkable differences of structure as suiting each to its proper locality and office, yet there is not the slightest tendency to blend the two characters of any two classes in one and the same individual. This fact might have been arrived at from what has all along been observed of species, and species which, in structure, in food, and in habits, approximate very nearly to each other. From the great proximity between some of these, we may conclude not with probability only, but with certainty as great as can be obtained upon such a subject, that they could be blended together far more readily than the characters of two classes; but we find that the line of distinction between species and species is so clearly drawn, and so impossible to be permanently broken, that not one new fertile species partaking of the characters of two separate ones, can be introduced by all the skill of the cultivator of animals, though he labours with the utmost assiduity for the express purpose, inasmuch as the animals of one generation which he procures by this means, possess qualities which, for certain purposes, are more estimable than those of the pure animal of either species.

If this holds true between species which are so nearly allied to each other, and in all probability are so nearly from the same original pastures as the horse and the ass, the argument thence arising ought surely to have been sufficient to show that there could be no such blending as that which was alleged in the case of those animals, and more especially in that of the ornithorhynchus, which was the earliest and the best known.

Other arguments, all tending to the same effect, might have presented themselves in formidable array; for if there are any animals which have less occasion than others for any of the attributes of birds, they are the very ones under consideration. Flying is the proper bird character; and flight might be much more useful to, and therefore might be expected to be sooner given to a mole or an otter than to either of those animals. Besides, when birds lose their proper function, the capacity of flying through the air, they lose in a great measure those parts of their bodies which are the proper organs of flight. If they are swift-footed animals, they have rudimental wings and downy feathers, which serve them as balancers; and if they are slow-footed, the bones of the wings are hardly, if at all, produced beyond the skin of the side. If the wings are to be used as swimming organs, as is the case with those aquatic birds which are incapable of flight, there is a peculiar modification to fit them for this office; but there is in no case the slightest tendency in the wing of a bird to take the shape of a toed and clawed foot, as we find both in the ornithorhynchus and the echidna.

The skeletons of both animals are strictly those of mammalia; and in the articulations of the legs, there

is no approximation to the articulation of the quadruped reptiles, which, whether they move fast or slow, always have the joints of the legs turned in a very peculiar manner, so as never to be mistaken for animals of any other class.

There is another circumstance which probably tended to mislead those naturalists who looked too exclusively to the facts immediately before them, and the analogies of the mammalia, without due attention to those of the marsupial ones. It was not then known that the mammary teats of these animals are deciduous, or that they shrivel, the apex dropping off and the glands being completely absorbed, when not required; and it is highly probable that no two young ones are ever nursed upon the same teat of a mother, that is to say, in successive generations, whether the one generation follow the other ere that other is yet completely formed, or whether years, or longer intervals of time, may come in between them. This being the case, it is evident that no conclusion could be drawn from the total absence of teats in the female ornithorhynchus, unless these animals should be found accompanied by young, and without this apparatus. The number of these animals are so few, and their habits and modes of life are so difficult to be observed, that though an individual now and then was occasionally found, the searchers for them did not meet with a gravid female, or a female accompanied by very young offspring. This, of course, left the case open to conjecture; and as ornithorhynchi have been seen about some of the pools of the Australian streams, and eggs found in the banks soon afterwards, without any animal being observed to which those eggs could belong, there was the evidence of juxtaposition in favour of their being the eggs of the ornithorhynchus. This same juxtaposition is a very treacherous argument in natural history; and if we obtain nothing from analogy to bear it out, and especially if we have anything from analogy positively bearing against it, we cannot use it with anything like safety; and this turned out to be very remarkably the case with the supposed eggs of the ornithorhynchus. More careful inquiry succeeded in obtaining the young with the mandibles so short as to form a mouth capable of sucking, though one of very singular shape; and though the evidence has not yet been carried that length, it is by no means impossible that, at an earlier stage the young ornithorhynchi may be so formed as to be able to adhere to the teats of the mother, in the same manner as the other marsupial animals. The following is a portion of the account transmitted to the Zoological Society of London, from the Honourable Lieutenant Maule, who, in common with very many officers both of the British army and the British navy, placed on foreign stations, is now cultivating natural history with equal assiduity and success. We quote from the proceedings of the Society's Committee of Science, to which committee the information was first communicated. "During the spring of 1831," writes Lieut. Maule, "being detached in the interior of New South Wales, I was at some pains to discover the truths of the generally accepted belief, namely, that the female *Platypus* lays eggs and suckles its young.

"By the care of a soldier of the 39th Regiment, who was stationed on a post at the Fish River, a mountain stream abounding with *Platypi*, several nests of this shy and extraordinary animal were discovered.

"The *Platypus* burrows in the banks of rivers, choosing generally a spot where the water is deep and sluggish, and the bank precipitous and covered with reeds, or overhung by trees. Considerably beneath the level of the stream's surface is the main entrance to a narrow passage which leads directly into the bank, bearing away from the river (at a right angle to it), and gradually rising above its highest water-mark. At the distance of some few yards from the river's edge, this passage branches into two others, which, describing each a circular course to the right and left, unite again in the nest itself, which is a roomy excavation, lined with leaves and moss, and situated seldom more than twelve yards from the water, or less than two feet beneath the surface of the earth. Several of these nests were, with considerable labour and difficulty, discovered. No eggs were found in a perfect state, but pieces of a substance resembling egg-shell were picked up out of the *debris* of the nest. In the insides of several female *Platypi* which were shot, eggs were found of the size of a large musket-ball and downwards, imperfectly formed however; i. e. without the hard outer shell, which prevented their preservation."

The eggs, without any shells which Lieut. Maule describes as having been met with in female ornithorhynchi were no doubt the young, in a state probably sufficiently far advanced for being ready for their external destination; but it does not appear that there is any thing which can decidedly connect the substance resembling egg-shell either with the mother or with the young.

It must be borne in mind that the question here is not whether the primary rudiment of the ornithorhynchus is or is not an egg; because the rudiment of every known animal is an egg; and the question is only as to the state of development in which this egg is when it leaves the body of the parent animal. In the true mammalia the maturing is internal; and though the young are in different degrees of perfection at their birth, according to the nature of the species, they are always sufficiently developed for being capable of sucking the mother by means of the mouth. In the marsupial animals it is probable that there are also differences of development in the young of different species, when they leave the internal uterus; but they leave that uterus without any distinct development of parts, and therefore without the capacity of performing any of what are called the voluntary functions of animals. They have no mouth formed, although they have a means of attachment to the nipple; and until they have a mouth, and can quit and regain the nipple at pleasure, it is highly probable that the nourishment they receive from that organ is not milk suited for the purpose of ordinary digestion, and requiring the action of the air in breathing before it is fit for the purposes of life: but that it is a fluid derived immediately from the unchanged arterial blood, and therefore requiring no more breathing or action of the air in the young which receive it, than the nourishment of the true mammalia require while they are in the uterus. Indeed the arterial structure of the hinder parts of these animals is such that the same supply of arterial blood may go either to the uterus or the teats, or that it may go in part to both at the same time.

We must therefore consider the marsupial teats as having somewhat of a placental character, as long as the young adhere to them, and are formless. It should

seem, however, that a change takes place in those organs, in the latter stage of the marsupial gestation ; and that glands, capable of secreting milk, but differing from the permanent mammary glands of the true mammalia, are produced at the proper time for the purposes of the young.

That these glands are not conglomerate, like those of all the land mammalia, which bring forth their young alive, does not prove that they are not milk glands ; for the mammary glands of the cetaceous mammalia are not conglomerate, but consist of little tubes which open at the one extremity, but are closed at the other ; and in the cetacea the walls of these are capable of secreting a milk which is as rich as ordinary cream. It has been mentioned by several observers in Australia, that these glands do contain milk ; and that they appear sufficiently developed, this milk is found in them, and can be extracted from them by pressure, only at those stages of the animal's economy, when the milk is necessary for the young.

Those observations have been made with such care and reported with such accuracy, they have been examined with so searching an analysis, and glands analogous in situation to these, in shrews and some other animals, have been shown to be developed at times and for purposes so different, that the fact of the ornithorhynchus suckling its young, for some time at least, may be said to be completely made out ; and the establishment of this in the case of the ornithorhynchus is tantamount to the establishment of it in the case of the echidna.

There still remains, however, the question of the degree of development which the young have when they leave the internal uterus. If they are in the state of eggs, as we properly understand eggs in birds, and in those oviparous reptiles which produce perfect eggs, and do not hatch them internally, then there is no instance of the contents of such an egg, when perfect, being incompetent to bring the contained animal to a state of maturity, if placed in the proper circumstances. It is true, that pigeons and some other birds feed their young partially upon a secretion of the stomach ; and that almost all birds, except such as feed their young upon the most succulent and easily digested food, prepare the food in part by the lubricating and solvent juices, by means of which they prepare their own food for the stomach. This, however, is a very different operation from suckling, and it is performed by a different apparatus, namely, the common apparatus which the animal has for its own feeding ; while the milk glands of the ornithorhynchus are prepared for an express purpose, and at an express time ; and therefore, whether the young when brought from within are more or less developed, or required to depend a longer or shorter time on the mammary apparatus, we cannot, without violence to the general analogy of nature, and the introduction of organs for which there is no use, hesitate to admit that the ornithorhynchus and the other monotrematous animals follow the general law of the marsupial animals ; and differ from the others in adaptation to that law only in so far as the fitting of them in the best manner for their very peculiar habits is concerned.

The following cut will furnish some idea of the figure of the ornithorhynchus when making its way through the water ; and we have added the foot on a larger scale, in order to show the curious management of the web, by means of which this foot becomes

alternately an efficient swimming and an equally efficient digging instrument. It will be observed that the web is capable of being stretched even beyond

the extremities of the claws ; but it is also true that it can be retracted, or turned upward upon the upper side of the foot, so as to enable the animal to dig in the earth with great force and activity, for which purpose it is otherwise well adapted, in consequence of the shortness, the strength, and the articulation of its fore legs. In the quotation from Lieut. Maule, the situation and form of the nest are described, so that it is unnecessary to advert to these ; and it should seem that the food, in great part at least, consists of worms, and shell-less aquatic mollusca. The echidna, on the other hand, being a land animal, and having the mandibles and tongue differently formed, is a feeder upon insects. Leaving, however, those curious animals, we shall now very briefly advert to the rest of the marsupial animals, in order that we may trace the particular divisions of the common mammalia to which they have the greatest resemblance. We have already offered some observations on the opossums, and shown the correspondence there is between them and the insectivorous division of the common mammalia ; and the grand difference in their habit is that the opossums are more the inhabitants of trees, and the insectivorous mammalia are more the inhabitants of the ground. This throws them upon different latitudes of the earth for their pastures ; the opossums being found in the American continent only ; only one out of the warm latitudes, and that one not reaching the cold ones ; while the insectivorous mammalia which possess the three kinds of teeth, and therefore range properly as carnassiers, are most abundant in the temperate or the cold latitudes ; and their place in the warm latitudes is supplied by the ant-eaters and the analogous genera, assisted by insectivorous reptiles, chiefly saurians, whose structure and covering fit them for activity in warm countries only.

Simple as it may seem, there is a very beautiful adaptation to other parts of nature, in this geographical distribution of those two classes of animals. Climbing insectivora would interfere with the summer pastures of the birds in the deciduous groves and forests of temperate countries, because the tree insects and their larvæ supply those birds with their proper food ; and, on the other hand, animals constructed like these ground mammalia would not be well adapted for breaking open the strong castles of the tropical ground insects, and levying such contributions upon the inmates as to preserve the proper balance of the numbers. The soft-billed birds, and

this is the character of the greater number of our summer visitants, are just as badly fitted for breaking open those strong castles; and therefore, while the tropical countries contain the most abundant supplies of food for the anteaters and other strong clawed edentata, they would be a desert to those birds which visit us during the summer. It is thus necessary to the proper working of the general system of nature's economy, that our insectivorous mammalia should keep to the ground; and it is just as necessary that those of tropical countries should be capable of climbing.

The *Dasyuri* (which name is derived from their tails being hairy or woolly and not prehensile) are the true carnivora of New Holland; but they have not any thing like the strength or the courage of mammalia of the same size; and they are indiscriminately feeders upon insects, such warm-blooded animals as they can master, and carrion and all manner of animal garbage which they can pick up. Their leading characters are, eight incisors in the lower and six in the upper jaw, all small and regularly arranged; large canines in both jaws; six grinders on each side of both; the two anterior ones compressed, and with trenchant edges like the true carnivorous teeth of the mammalia, and the ones behind with insectivorous or sharp points besetting their surfaces. There is something in the structure of this mouth which renders it less carnivorous than the mouth of the mammalia with which the animal most nearly corresponds. In them the false molars come in between the canines and the great carnivorous teeth, and thus each of these can perform its work, separated to a distance from the other. The canine is by this means more completely a wounding or killing tooth, and the carnivorous more completely a cutting and tearing one; further, as the tearing tooth comes in close juxtaposition with the wounding one, those animals have what may be called a more dangerous mouth than the carnivora; and though they are not so capable of wounding, they mangle a good deal more. Another thing which lessens the power of these animals is the concentration of a great portion of their energy upon the large and powerful tail, and on the marsupium and its apparatus; and their speed is diminished by the possession of more perfect clavicles than are possessed by any of the carnivorous mammalia, and especially by those which are fleet footed.

Perhaps the most characteristic of them, though it differs so much from the rest as to be considered a different genus by some naturalists, is an animal about the size of a wolf, of a yellowish brown colour over the body generally, and streaked with cross bars of black across the back. This has been found only in Van Diemen's Land; and it has been termed *D. cynocephalus*, or the dog-headed dasyurus. The name, however, is not a very correct one, as the air and even the shape of its head are by no means like those of any species of dog, and the ears are short, erect, and rounded. Neither this nor any of the others is capable of climbing, and therefore they are reduced to seek their food upon the ground; and this one is known to prowl much about the wild shores of Van Diemen's Land, and pick up such animal refuse as is cast on the beach by the sea, or brought down by the floods during the rainy season. The other species, or perhaps the members of the other genus, have different characters. Their bodies

and also their heads are longer in proportion; and their tails are covered with much longer hair. The largest of them has the coat very shaggy, something resembling that of a bear; others are smaller, less shaggy, and not so dark in the colour; and some of them are very small. These animals are much disliked by the colonists who reside in the neighbourhood of their haunts; and they are accused of committing considerable depredations on the flocks of the colonists; but it is probable that a good deal of the injury of which they stand accused is perpetrated by the bushmen, and the dingo, or half-savage dog, which is much more likely to do injury to flocks than those prowling, cowardly, and comparatively feeble animals.

The genus *Perameles* (so named from a certain fancied resemblance to badgers) are still to a considerable extent carnivorous. They are ground animals, and certainly answer in their manners to the badgers of other countries; for they are expert at digging in the ground. These animals, like all animals which are expert burrowers, have the muzzle long, the head slender, the ears so placed as to turn down upon the nape, the hair of the body short, and the tails much more slender than those of marsupial animals in general. Their hind feet are much longer than their fore ones; and they are formed something like the feet of the kangaroo, so that they can either spring from the toes or from the whole length of the tarsus. The external and internal toes on their fore feet are reduced to mere tubercles, so that their feet appear only to have three toes, which toes are, however, well adapted for digging, and furnished with strong claws. The thumb on the hind feet is very short in comparison with the others, and the two middle ones are generally united by membrane, so that they can offer a firmer point of support than could be given if the toes were entirely divided. The females are provided with a pouch (*pera*), so that *perameles* is merely a translation of "pouched badgers," the name given them by the settlers in Australia. As these animals are still more obscure in their modes of life than those to which we have already alluded, we are less acquainted with their feeding. It is probable, however, that the greater part of their subsistence consists of ground insects, and other small ground animals.

Those which we have now enumerated comprise all the marsupial animals which have any part of the mouth decidedly carnivorous, though it may be said that the insectivorous character predominates in the whole of them, being that of the greater number of their cheek teeth. We cannot therefore regard them as being set, like the true carnivorous mammalia, to watch over and regulate the numbers of an extensive and varied population of mammalia; this accords with the character of the country in which the vegetable feeding marsupial animals are not very numerous, and in which, until they were introduced, there were hardly any true mammalia.

Of the remaining division of marsupial animals, some bear a slight resemblance to squirrels, at least in some of their habits, and very partially in some parts of their structure; but the greater number may be said to have hardly any types among the true mammalia. Some of them live almost exclusively in trees, in the holes of which they form their nests or other abodes; and many of them are furnished with parachute membranes along the sides, by means of

which they leap about among the branches with great agility.

The genus *Phalangista* (the phalangiers), as already hinted, are not confined to New Holland, but consist of two sections, one with the tail naked, but prehensile, and the other with the tail hairy, but prehensile as well as that of the other.

These animals, and indeed the whole of this division, are chiefly vegetable in their feeding, though there is perhaps none of the marsupial animals exclusively vegetable. These animals have, however, their intestines longer, and more furnished with caecal appendages than those formerly noticed; and thus it follows that their general food is more difficult of digestion. They have the thumbs large and directed to the rear, something in the same manner as the hind toes of birds. This thumb is without any claw, and two of the toes of their feet are often united as far as the second phalange. It is this which caused them to get at first the name of phalangiers; but it is not a very happy name, inasmuch as the last mentioned genus, though without thumbs, have the toes united in a similar manner; and the Malay name "pelandor," which resembles this one, and is sometimes mistaken for it, is one which we would translate rabbit, though it is said in many of the oriental islands to be applied to a small leaping animal having many of the characters of a kangaroo.

The character of these phalangiers, and of another genus or subgenus closely allied to them, as dependent on the mouth, are: two very long and strong incisive teeth in the under jaw, acting against six smaller ones in the upper. This produces a slight resemblance to the rodentia; but the edges of the cutting teeth are of a more tearing and less gnawing structure than those of the rodentia. They differ from these animals also in having the upper jaw always furnished with long and pointed canines; but the canines in the under jaw are not longer than the false grinders.

The chief distinction between them, which is decidedly different from the allied genera, is the want of parachute membranes along the sides. Still they are expert climbers, and search the trees with great diligence and rapidity; and they are exceedingly dexterous in suspending themselves by the tails from the branches of trees. They have a rank and offensive odour; but, notwithstanding, they are eagerly sought after as food by the inhabitants of those countries in which they are found; and in New Holland they are eagerly hunted, both by the natives and the colonists. The trees of New Holland are remarkably well adapted to the habits of animals of this description. Very many of them are hollow; and as soon as the central wood of a tree begins to decay, the wood-consuming insects, known by the general name of white ants, come in countless myriads to clear it away. Such animals as those of which we are speaking come first to levy their contributions upon the insects, and then to take possession of the cavities, so that the hollows of the trees form ready-made burrows for these animals. The natives are, however, very expert at scaling the trees and drawing them out or dislodging them by means of smoke. The species which inhabit the Oriental Archipelago do not live so much in hollow trees as those of New Holland; because the trees there are not so subject to decay, and the animals are in consequence more among the branches.

These animals, from the possession of the pouch, have been called by the general name of opossums; but the individuals have been named after any animal which it struck the fancy of the namer that they nearly resembled. The largest of them is about the size of a full-grown cat, the others are smaller.

The allied genus *Petaurus* (the flying phalangiers or those with the lateral membranes) differ from the others in these membranes, in the greater pointedness of the nose, in having the feet more capable of cross motion, and in the tail not being prehensile. They are very active animals among the trees, and can support themselves for some little time in the air by means of their parachutes, though they are of course quite incapable of gaining a fresh impulse from that element. The teeth of these animals are very insectivorous, their molars next the canines being very pointed, and the ones further back in the mouth terminate in four sharp points, so that no part of the mouth of the animal is adapted for bruising vegetable matter.

The most characteristic, or at all events the largest animal of this section or genus, is the great flying phalanger. The total length is about twenty inches. The head is small and very pointed at the muzzle; the ears are large, of an oval form, and covered with hair; and the tail, which is round at the basal parts, though flattened in the length, is very thickly and finely beset with hairs. The general colour of the body is of a greyish brown colour, paler on the sides of the lateral membrane; and the head is nearly the same colour, with bright yellowish brown hairs down the middle of the forehead. It inhabits the woods on the eastern coast of New Holland, especially the rich district between Port Jackson and Botany Bay.

Another species, the long-tailed flying phalanger, is about a fourth larger than a common rat, with the tail slender and half as long again as the body. It is greyish brown above, and whitish on the under part. The tail is black for the greater part of its length, but paler towards the body.

Another species, of a greyish brown colour, and with the toes furry, having a black tail with a white tip, also inhabits New Holland. The most remarkable of the whole, however, is the little flying phalanger, which is not more than two inches long in the body; and yet by the help of its parachute it can leap to a very great distance as compared with its size. The most remarkable character of this little animal is the tail, which is formed with hairs regularly disposed on each side, arranged like the webs of a quill; and there is no doubt that this form of the organ assists the animal greatly in performing its leaps.

There are some other species found in New Guinea and the adjacent isles; but it does not appear that any of those which are furnished with parachutes are found so far to the northward as the species which are without this appendage. They differ considerably in size and colour; but there is a strong likeness among the whole of them, and it does not appear that there is any very great difference in their manners. The genus *Petaurus* is known by the name of the kangaroo rat. The cutting teeth are the same in number as those of the last, with those of the under jaw very long. The canines are also wanting in the under jaw, but those in the upper are long and pointed. Immediately behind the canine they have a large molar with a trenchant edge, though the

other four have their crowns marked with four rather smooth tubercles. These circumstances indicate a certain degree of the carnivorous character, though not a very decided one; and their digestive organs, and also their cheek teeth, indicate a more vegetable habit than any of those which we have already described. In their forms they bear a considerable resemblance to the kangaroos; and the chief difference consists in their having canines in the upper jaw. The hind legs are very long as compared with the fore ones; the thumbs are entirely wanting, and the first and second toes are closely united up to the nails, which gives them the appearance of having three toes on the hind foot, with two nails on the inner one. They can walk, or rather leap, upon the two hind feet, and use their fore paws something in the manner of hands. The size of this animal is about the same as that of a young rabbit, and its colour resembles that of the common shrew. Illiger gave it the name of *Hypsiprymnus*, which means elevated on the hind legs, or at the crupper; and Shaw and some others classed it with the kangaroos, from which, however, it is evidently distinguished by the canines in the upper jaw, and the unequal length of the incisive teeth in the same. It is, however, what naturalists are in the habit of calling a link between the phalangers and the kangaroos, partaking much more of the general form of the latter, but agreeing with the former in the general structure of the teeth, with the exception of the particulars that have been noticed. There appear to be several species of this animal, or more strictly speaking varieties, inasmuch as almost their only differences are those of size and colour, which may be produced by mere difference of locality.

The kangaroos may be said to form the last genus of this part of the marsupial animals; and they are the most decidedly vegetable feeders of the whole. Their front teeth are the same as in the last mentioned, and their cheek teeth are the same in number, but they are entirely without canine teeth, and in their native locality they subsist entirely upon vegetable matter. Both they and the last mentioned species have the stomach divided in two separate sacs. Their general structure and manners have been noticed, accompanied by an illustrative figure in a former part of this article; and some account of the species and popular notice of their habits may be seen in the article KANGAROO; so that we need only mention further in this place that they are not confined to New Holland, but that some small ones at least occur in the Molucca Islands, where they are called rabbits by the Malays. *Macropus* (large foot) was the generic name given to these animals by Shaw, which Illiger proposed to alter for *Halmaturus* (leaping tail), which is the more correct name of the two; because, though some other leaping animals have the hind legs proportionally as long as the kangaroos, there are none which make so much use of the tail in leaping.

Only two genera of the marsupial animals of New Holland remain to be noticed; and each of these requires to be formed into a separate section. The first, the *Koala*, has six cutting teeth above and two below, as in several of the genera already mentioned; two false grinders above and none below; and four other grinders in each jaw, but with two tuberculous protuberances on the crown of each, and not in any respect the true grinding crowns of the vegetable

feeding mammalia. The claws in this animal are sharp and rather crooked; and they spread out so as to act against each other in the same manner as the feet of squirrels. The animal climbs readily, but does not leap expertly. The young are brought forth in their early stage; but as carrying it in a pouch, or on the under side of the body, would not suit the climbing habit of the mother, it is carried on the upper part of the neck, to which it clings firmly, and the mother is enabled to climb without any danger of its falling off. Besides climbing, the animal burrows expertly, and its food is understood to be almost wholly vegetable, consisting of dried grass and withered stalks of plants. It is an exceedingly inoffensive animal. The generic name *Phascolarctos* means a bear furnished with a pouch; but there is very little of the character of the true bears either in the appearance or the habits of the animal.

The WOMBAT (*Phascolomys*—pouched rat) is the last which is yet known, and it is one of the most peculiar animals of the whole. It agrees in the general character with the rest of the marsupial animals; and therefore there is no question as to its belonging to this order or sub-class of the mammalia. It does not, however, agree in the usual characters of classification, as for instance in the teeth, or in the articulation of the jaws. The lower jaw is articulated with a mere opening and shutting motion in the manner of the carnivorous animals, and wants entirely the grinding action by a slight backwards and forwards motion, which characterises the rodentia. The teeth in the front of the mouth are two in each jaw, very stout, short, thick, and flat, the upper ones inclining towards each other at their extremities, and both rounded off so as to present oblique oval discs, with a rounded edge to the front. There are no false grinders or canines in either jaw; and the number of true grinders in each is five, with flattened oval crowns, but divided by a central furrow across the middle of each. Although, therefore, the mouth of this animal does not exactly resemble that of the typical rodent mammalia, which are not marsupial, yet they approach nearer to these than to those of any other animals. The wombat is plantigrade, with four toes on all the feet, only the thumbs on the hind ones are mere tubercles; and the claws are long and strong, and well adapted for burrowing. The ears are very small, and almost concealed among the rough fur of the animal; and the eyes are also very small; both circumstances indicating that the animals are habitual burrowers in the ground. They appear to be among the most passive of the mammalia. They can be tamed, or rather they will live with those who feed them; but they show nearly equal indifference to good and bad treatment; and though perfectly harmless, they seem incapable of being turned to any useful account, farther than that of being eaten, for which purpose it is said that their flesh is not badly adapted; and as their food is entirely vegetable, and their lives spent with exceedingly little labour, it is by no means improbable that this may be the case, though enough is not known of their habits for enabling us to judge whether their productiveness is such as would render them of much, or even of any, value in a state of domestication. With these animals we shall close our brief examination of the marsupialia; and we have made that enumeration rather less brief than it might have been, in order to save the space that would be occupied by a separate article MARSUPIALIA.

in its place in the alphabet; and we trust that what has been stated here will render a mere reference from that word to this article quite sufficient for all purposes to the common reader.

We could have wished to be able to state more clearly the relations of those marsupial animals, to the ordinary mammalia as well as to each other; but so many anomalies present themselves in both of these respects, that it is doubtful whether, in the present state of our information concerning them, an increase of words would produce any increase of knowledge.

CETACEA. This is the last order of mammalia in the view which we have taken of them; and indeed, in strict propriety, they belong to the true mammalia, and therefore should precede the marsupial animals; but it is sometimes convenient to sacrifice a little of the structural arrangement of animals, for the sake of that part of the arrangement which guides us to their localities; inasmuch as, without the study of the locality, as well as the organisation of the animal, we are furnished only with half the lesson of wisdom which the animal is calculated to afford. Indeed we cannot properly appreciate the structure, without taking the locality along with us; because the organs of motion, and the external parts generally, are adapted to the locality; and the internal parts are necessarily adapted to the external, in order that the animal may be one complete and symmetrical whole, and not an assemblage of parts incongruous to each other.

Now, all the mammalia of the orders which we have already noticed, whether placental or marsupial, are, to some extent or other, land animals; for even the amphibia, the seals and the mooses, which are more completely formed for the water than any of the rest, can, and do, lie on the banks and rocks for hours at a time, enjoying themselves in the air and basking in the sun; and the others, whether placental or marsupial, which find the whole or the greater part of their food in the waters, are more decidedly land animals, and capable of ranging to some distance over the dry surface. The otter, for example, is rather a fleet walker; and the palmed opossum, though not quite so fleet, is still a tolerable walker. Even the ornithorhynchus, slow as it is, can get on faster than some of the toothless animals which live habitually upon the land; and thus, though they all differ by shades greater or less, there is none of the mammalia belonging to any of the preceding eight orders which has not some capacity of action, both on the land and in the water.

The cetacea, on the other hand, though true mammalia in the whole of their internal structure, and in all the essential points of their economy, considered without reference to the element in which they reside, and for which alone their external form and their organs of locomotion are adapted, are, in consequence of this adaptation, perfectly helpless on the land, or even when they ground on the shallows in such a manner as not to be able again to get afloat. Some of that section of them which are herbivorous, and, as such, approach a little nearer to land, or at all events to shore animals than the cetacea of the sea, can contrive to shuffle a little way up the shallow and back again, in the course of their feeding. But the characteristic cetacea, which are those of the sea, though they do not die for want of breathing, as a fish does which breathes through the medium of water, are yet so perfectly helpless

when stranded by accident, that they very speedily perish for want of food, or in consequence of the injuries which they do themselves in their attempts to get off. This draws a perfect line of distinction in point of locality between them and every description of the land mammalia, and completely justifies the considering them as separate from all descriptions of the latter, whether they are, in the physiological character upon which the distinction is founded, equally true mammalia with the cetacea or not. The cetacea claim our separate attention upon other grounds: they are by far the largest and most powerful of all the mammalia; and their pasture is wider in proportion. Setting aside those which frequent the fresh waters, their pasture is in mere extent full two and a third times as great as that of the land mammalia: and when we consider that much of the land is unfit for the support, or even for the travelling, of any mammalia, we are constrained to admit that these animals have many times the range of any or all of those of the same class which inhabit the land only. We do not mean to say that their numbers are greater; because, they are all large animals; and we find, upon examining the land mammalia, that, unless in the case of genera specially adapted for confined and peculiar localities, their numbers increase nearly in the same proportion as their size diminishes.

In the article **CETACEA**, in its alphabetical place in this work, we went into considerable details, both of the general structure and species of these animals; and in a preceding section of this article we had occasion again to revert to their organs of swimming, more especially to that most powerful organ of the whole, the tail of the black or Greenland whale. In consequence of this, it will be necessary only to give a few hints in this place, in order that our analytical list of the orders of the mammalia may be complete, and that for purposes of general comparison, and for inferring from this comparison the relative importance of the different mammalia, the reader may not have to refer from this general article to any particular ones, which reference might disturb his comparison.

Generally speaking, then, the cetacea are mammalia, without a single external vestige of hind feet or legs; and the whole of the posterior part of their body is concentrated into a thick and powerful but tapering tail, which ends in a great cartilaginous lobe, which is placed horizontally, or in a cross direction to that of the caudal fin of fishes; and though their neck consists of the same number of bones as that of the longest and most supple neck of the land mammalia, those bones are so exceedingly short, and so totally without motion upon each other, that there is no bending in any direction of the head in respect of the body, and no bending of the body in the part anterior of the fore-legs. The structure of those legs has been explained in a former section, when it was shown that externally they have the form of a sort of fins, though they still retain so much of the action of the anterior of land mammalia, as to be capable of clasping, and also of striking, and that with considerable force. Their brain, though small in respect of the head in many of the species, is still of considerable size, and the parts of it well developed; but the external organs of the two principal senses, those of seeing and hearing, are small, there being no external ears; and the eyes, though clear and expressive, being very minute

as compared with the size of the animals. From the position of the swimming fin, or lobe, on the extremity of the tail, that organ strikes the water upwards and downwards; and thus it is equally efficient for ascent and descent as for progressive motion. Cuvier was the first who collected the whole of the cetacea into one order according to their organisation, by separating the herbivorous ones from the morses, with which they had been previously confounded. The general structure of these, as adapting them to their element, is the same as that of the more characteristic ones, the difference consisting chiefly in the adaptation of their feeding organs to food of a different description, namely, food which requires to be ground, or rather bruised, by teeth, instead of being conveyed entire to the stomach, and wholly assimilated by the action of that organ in the viscera, as it is in all the rest of the cetacea. They thus may be formed into two families, and those very natural ones,—the herbivorous and the ordinary cetacea, as they are most characteristically named by the great naturalist who first established the order on its proper structural basis.

Herbivorous cetacea. All the teeth of these have flat crowns, which is the truly herbivorous character; and the swimming paws of some of them are furnished with little claws or nails, by means of which they can crawl or climb wholly or partly out of the water, so as to reach and feed upon the grass or other vegetation near the margin. The females have two pectoral mammae; and both sexes have whiskers of produced hairs, which gives them, when half out of the water, a very slight resemblance to human bodies; and there is little doubt that this resemblance, in animals which are rarely seen, except in parts of the world very imperfectly—and we may add fabulously—known to the ancients, gave rise to all the ridiculous stories about sirens, and tritons, and mermaids, and old men of the sea; nor is it at all unlikely that the type of Father Neptune of the old mythology, and that of the Davy Jones of modern sailors, were borrowed from well-whiskered veteran animals of this family. Now, though they are large animals, they are exceedingly harmless; though those which live upon sea-weed may be more active, and come nearer the shores when a storm is about to loosen their food; for it is a very general instinct of animals, both of the sea and of the land, to feel the circumstances which bring them a supply of food, and to arrive at the place in order to receive it. We are far from saying that the animal has any knowledge of what is coming, in the sense in which we use knowledge as expressive of mental judgment founded upon reasoning from experience. So far from this, that we feel perfectly sure that no animal has any knowledge of the future, or even of the past, in the sense in which we use the word, and sometimes apply it incautiously to them.

It does not follow from this, however, that these and many other animals may not foretell to us the coming of storms, or other changes of the weather; for there are many such indications, in which no animal is concerned. When the light cirri play in more than ordinary numbers and activity in our summer sky, or when the moon shows a zone of gummy light in the winter, the chances are many to one that we shall have foul weather; and yet surely nobody will pretend to say that either the light clouds in the upper air, or the peculiar reflection or refraction of the moonlight which forms the lunar zone, can have

any knowledge of the weather. The indication which they give, belongs, however, to the very same class as that given by animals, whether of the land or of the waters.

There is a considerable difference between the breathing of those herbivorous cetacea, and that of the true ones. The latter breathe through apertures in the top of the head; and thus they can breathe though the muzzle is entirely under water. In the herbivora the openings come through the bones of the head nearly in the same manner as in the others, though, as the fore part of the head does not require to be largely produced for the same purpose as in the others, they rise nearer the termination of the muzzle. They do not, however, open even there, but descend to nostrils placed in the front, so that cetacea of this kind cannot breathe without raising the muzzle, in part at least, out of the water; and thus they do not require the blowing apparatus of the other cetacea.

Their organs of digestion correspond with the herbivorous character of the teeth: they do not ruminate, but their stomach is formed into four sacs, two of which are continuous and two lateral; and the intestine is furnished with a large caecal appendage. There are three distinct genera of those herbivorous cetacea. The first is the *manati*, which name has been corrupted to *lamantin*. Of this there are two species, one of the tropical rivers and estuaries of America, and the other of the rivers of the corresponding latitude in Africa, both of which rivers discharge their waters into the tropical Atlantic; and it is not understood that either of these species is found in any other part of the tropical waters. In the Amazon on the one hand, and the Senegal and the Gambia on the other, they are exceedingly numerous, more especially in the former, where, at the distance of more than fifteen hundred miles from the sea, they supply the people regularly with abundance of animal food of most excellent quality, resembling veal in appearance, but much more juicy. The animal is the *vacca marina*, or sea-cow of that part of the world, and approximates in value to the land cow.

The second species is the *Dugong* (*Halicore*, daughter of the sea), of the north eastern parts of the Indian Ocean and the oriental Archipelago. The mouth of this genus differs considerably from that of the former; for while the *manati* when full grown has only eight teeth with square flat crowns, the *dugong* has eight conical ones, united two and two, and the tusks are more persistent. This animal is not described as attaining so large a size as the former, which often exceeds twenty feet in length; but its flesh is not inferior in quality.

The only other genus is the *stelleræ*, which has been observed in the northern parts of the Pacific. It is different from the others, more exclusively marine; and it is understood to feed exclusively on seaweed; and it has but one tooth in each side of both jaws, which tooth consists of a plate of some extent, furnished with ridges of enamel fitted for bruising. Its stomach is more simple than that of the other two genera; but its cæcum is very large. Less is known respecting it than respecting the others, because it more rarely makes its appearance on the shores; and its paws are not provided with those claws which enable the others to crawl up the banks, as the ordinary cetacea.

As these are better known, and have been alluded to already in the course of this article, we shall do

little more than enumerate the different families, of which Cuvier makes two, dolphins and whales. The dolphins comprise the dolphins properly so called, the porpoises, the narwhales, and a few others, all of which have the head small in proportion to the size of the body; and the whales contain the spermaceti whales, which have teeth at least in one jaw; and the whalebone whales, which are destitute of these instruments.

Such, in brief outline, are the mammalia, according to the arrangement of the most scientific naturalist of any age; and had we not already exceeded all ordinary bounds with the extent of this article, we should have felt desirous of adding two sections more. The first of these would have treated of the climatal distribution of the different orders, groups, and genera of the mammalia, both as affected by latitude, and by the physical character of the surface; and the second would have consisted of an attempt to trace something like a progressive history of the greater and more important divisions, including those which are extinct, and those which are entirely domesticated. The subjects of both these sections are, however, in great part anticipated, by remarks scattered through the different sections of this article; and therefore we shall not enter upon them, but shall conclude by pleading the great importance of the mammalia for the length at which we have noticed them, and earnestly recommending the farther and more minute study of them to every reader of the "BRITISH CYCLOPEDIA OF NATURAL HISTORY."

MAMMEA (Linneus). A South American fruit-tree belonging to the natural order *Guttiferae*. This is the *Mamsee* or wild apricot of the West Indies and the American continent. The fruit is large, about the size of a cannon-ball, and covered by a double rind, the outer tough and leathery, the inner tender and membranous. The flesh, which is firm and of a bright yellow, has a singularly pleasant taste and fragrant scent; but the skin and seeds are very bitter and resinous. It is either eaten fresh or cut into slices with wine and sugar, or made into a preserve. In Martinique the flowers are distilled in spirit, to which they impart their flavour, and form a liqueur called *eau-creole*. The wood is good and used for many purposes.

MAN. SEE **BIMANA**, and **MAMMALIA**, *Passim*.

MANAKIN (*Pipra*). A group of Dentirostral birds; and the last in Cuvier's arrangement, as possessing some characters in which they approach to the syndactylic birds, inasmuch as they have the two exterior toes united for about a third part of their length. The general characters of the groups are: the bill compressed, higher than broad, a notch toward the top of the upper mandible, and the nasal grooves large. Their tail and feet are short; in the general form of their bodies they bear some resemblance to the tits, but their manners are different. They are all natives of foreign countries, either of the oriental islands or of the tropical parts of America; and the beauty of the plumage in some, and the peculiarities of the habits in others, render them birds of considerable interest. The habits of the genera are, however, so different, that no one general description could be so framed as to include them all.

The three genera are: *Rupicola* (cock of the rock); *Calypomenes*, which have no English name; and *Pipra* (the true manakins). We shall take these in their order:

RUPICOLA. Characters: the bill of mean length, stout, slightly arched in the culmen, a little hooked toward the tip and notched, rather broader than high at the base, but compressed toward the tip. Lower mandible straight, notched, sharp pointed; nostrils basal and lateral of an oval form, partly open, but entirely covered with the feathers of the crest, which can be elevated in the form of a semi-circle, not unlike the crest of the hoopoe. Feet stout, tarsus as long as the middle toe; the toes four, three to the front, the external and middle are united to the second articulation, and the inner united to the middle at the base; the hind toe very strong, and furnished with a stout claw; the first quill drawn out in a thread shape and short; the second and third also shorter than the fourth and fifth. The tail short, and squared over at the extremity.

Only one species of this genus is distinctly made out. It is a native of tropical America, a mountaineer, or more strictly speaking a rock bird, and very peculiar in the place which it chooses for its dwelling.

In consequence of the violent internal action by which the northern Andes, that is the Andes of Peru, and that spur which extends from them towards the Caraccas, appear to have been formed, and the violent currents of water to which they have been subjected by the bursting out of lakes, and the violence of the seasonal rains, their surface is more diversified than that of any other portion of the globe of nearly equal extent; the water has in many places cleft channels with perpendicular banks, hundreds of feet in depth, so that it requires the light of a vertical sun to reach the bottom. In some places the softer strata have been excavated away from under the harder ones, thus forming natural bridges of the most sublime character, the chasms, cauldrons, and even cascades below which are so deep, sinuous, and impervious to the light, that they are as dark as Erebus. In countless other places, where the water has not been able to effect a passage through, or where earthquakes, and other agencies may have been at work, there are caves in great numbers, and penetrating so far into the rocks, that they cannot be examined except by torch-light. Those caves are the proper abodes of the rock birds. They occur in great numbers, and are found in the caves at all times; though it is understood that they fly indiscriminately by day and by night. In some of their other habits, besides this habitual dwelling in caves, they bear some analogy to our rock doves, which are understood to be the common parents of all the races of domestic pigeons. They live in pairs, are much attached to each other, and the males more frequently leave the caverns than the females do. The eggs are two in number, of a white colour, and not unlike those of pigeons; the birds are also about the size of pigeons, but they are not nearly so powerful on the wing. Their habit does not require it; for in the vicinity of the dark and damp caves of a country of such powerful natural action as that which they inhabit, there is an abundant supply of insect food at all times, without the bird requiring to range to any great distance at any time. And if this food should fail, they have recourse to the small fruits, which grow plentifully upon the trees and bushes.

But though they have the resemblance to pigeons, which we have stated, they do not belong to the same order; for they are insectivorous in their leading character. They are exceedingly active birds,

and very much on the alert ; and though the hunters of that country seek after them with great avidity, it is not easy to shoot them. Residing in the dark cave, even when that cave is not so pitchy dark as to require torch-light for exploring it, their eye sight is far more keen than that of the hunter, who enters from the clear and dazzling light of tropical sunshine ; and thus, notwithstanding all the wariness with which he endeavours to surprise them, the thunder of their wings, as they escape by thousands, is often the only evidence he has of their presence. In this again they bear some resemblance to the rock pigeons. These prefer a dark or twilight cavern to a more exposed situation ; and as the caverns which they haunt are chiefly those on the shores, in wild and lonely places, where they can be entered only from the sea, the sound of ten thousand wings passes over, and literally stuns any but the most experienced hunter in such places, before he has the slightest chance of getting a shot.

From the shortness and roundness of their wings, the birds in question are not air birds to any very great extent ; and they often alight upon the ground, and probably subsist in great part upon ground insects and larvæ. They scrape the ground something after the manner of poultry, of which they possess some of the gestures ; and these may have given rise to the inapplicable name of cocks of the rock. This name is inapplicable, inasmuch as they have not the voices, the general habits, or the fertility in a single brood of the gallinaceous birds. How often they may breed in the year is unknown ; but the circumstance of never more than two eggs being found in a nest, while the birds themselves are so very numerous, would lead us to conclude that they breed frequently. In the countries where they inhabit, there are no circumstances in the seasons which prevent the birds of the rocks or the woods from breeding at one season more than at another, because food is nearly in equal plenty at every season. As many of the birds of such localities breed only single pairs at a time, and repeat them often, and yet are seen in greater numbers than birds which are more fertile in the single brood, there is some reason to believe that this is the most favourable mode of breeding ; because although it extends more generally over the year, the food of a pair of young is, of course, obtainable with less exertion on the part of the parent birds than that of a greater number.

Though the nests of these rock birds are in the clefts and irregularities of the cave, they are formed of dry sticks, which the birds collect with considerable assiduity ; but it is probable that the same nest serves for many broods, as it is not exposed to the weather ; and as the birds are not of a ranging disposition ; the nest is usually very large in proportion to the size of the birds, in order, no doubt, to preserve the eggs and young from the cold damp of the rock on which the nest is placed.

These are rather handsome birds. The general colour is bright orange brown, inclining to red. The crest is formed of a double row of very close feathers. Some white appears in the middle of the wing, and the quills and coverts are brown, bordered with yellow. The greater number of the feathers are square at the ends, as if a part were cut off. The bill and feet are yellow. The length is about eleven inches. The female is less than the male, of a uniform greenish brown colour, and with a smaller crest. The young are dull brown.

Another species or variety is mentioned, inhabiting the same countries, and having the same habits and the same size, but with the quills and feathers of the tail dark brown or nearly black. It does not appear, however, that there is any difference between the two upon which a characteristic distinction could be founded ; and indeed it is more likely that the one with the black feathers is merely an accidental variety.

CALYPTOMENES. This genus, of which only one species is known, resembles the former in its general structure, and in part also in its habits ; but it is very different in appearance, and inhabits a part of the world almost diametrically opposite, being found in Sumatra, Java, and the adjoining islands. It is a much smaller bird, being only six inches and a half in length, and thus being not larger than a blackbird. Its colour on the upper part is bright emerald green, very brilliant and shining. There is a black spot on the ear cover ; and the coverts of the wings are black, with green tips, which form three beautiful bars across the closed wing. The primary quills are black, and the bill and feet brown. The female is grass green on the upper part, not so brilliant in the lustre as the emerald green of the male ; and the under part is paler green, clouded with darker patches. She is without the crest on the head, and the black bars on the wing coverts ; for only the tips of the quills and the inner webs are black. Both sexes are, however, very beautiful birds ; but generally speaking they live in places which have been little visited by Europeans, and accordingly their manners are but little known.

Both these genera differ in their appearance, and also in their habits, from the true manakins, though there is as much similarity as induced the elder systematists, who did not attend very carefully to all the characters, to include them in the same genus. They are sufficiently allied, and sufficiently different from any other of the denticrostral birds, for being formed into a group ; but there is no question about the division of this group into the three genera, of which we have now to consider the last.

PIFRA (the true manakins). These are smaller birds than any of the others ; but like them they are, generally speaking, remarkable for the beauty of their plumage. There are many species of them, but they are understood to be confined to the warmer parts of tropical America, and to the West India Islands. They differ so much from the others as to merit a separate generic description. Their characters are : The bill short, triangular at the base, where it is a little enlarged in breadth, convex in the upper mandible, which is notched, and pointed in the under one. The nostrils are placed at the sides of the base of the bill, covered in part by a membrane which is ornamented with little feathers : the feet are of mean length, but the middle toe is longer than the tarsus. The situation of the toes, and the union of the external and middle one, are similar to those of the two former genera. The wings and tail are short ; and the third and fourth quills are the longest in the wings. They are beautiful little birds, which remain during the heat of the day in the depths of the close forests ; and in consequence they are but little seen in proportion to their numbers. They inhabit peaceably ; and do not range over the open plains, or approach the plantations to display their bright colours, and levy their contributions on the gardens, unless when the

habitation happens to be very near the wood, which is their strong hold, and even then they do it but rarely. When seen they are always admired, in consequence of the purity and brightness of their colours, the apparent gentleness of their manners, and even their voices, which, though they cannot be called musical, are rather pleasant in their chirping. The early part of the day, before the sun becomes powerful, is the time when they are abroad feeding. At that time they appear in little flocks; but during the rest of their time they live detached, even the males separating themselves from the females. They are difficult to rear in confinement, and seem to feel the want of that morning society, which is very constant, though it occupies but a small portion of any one particular day. They feed indifferently upon insects and berries, but appear to prefer the first. They fly with considerable rapidity, but their flight is low and short. Their nests are formed in thick bushes and trees of low growth, and their eggs, as is the case with all very small birds, are numerous; and this forms another remarkable distinction between them and the rock birds of the South American caves—the number of a brood in the green bird of the oriental Archipelago has not been so fully ascertained.

The species enumerated by different authors are very numerous, but several of them rest upon questionable authority, and are in all probability the same species in the plumage of different ages. We shall enumerate a few of those which appear to be best made out.

Caped manakin (P. pileata) is well-established species, and has been found in Brazil, in the humid forests; but it probably exists in many other parts of America. The other parts are bright chestnut; the top of the head, the nape, and the quills, pure black; the wing coverts have an ash-coloured spot on their extremities, and the quills have greenish margins. The cheeks and a streak over the eyes are bright red. The tail is slightly wedge-shaped, with six feathers in the middle, blackish and brown at the tips. The lateral feathers are brown, with yellow bases. The under parts are russet. The bill and the feet yellow, and the length four inches and a half. The feathers on the head admit of being raised into a sort of cape rather than crest; and the female possesses this as well as the male, but it and the upper parts are greenish. Her wings are ash-coloured with grey spots, and greenish margins to the quills. The nest and manners in the forests are imperfectly known.

Red-fronted Manakin (P. rubifrons) is a smaller species than the former, being only about three inches and a half in length. The front and rump are red, the upper parts black, with yellow borders to the quills; the two middle feathers of the tail longer than the others, and straight; the cheeks and chin greyish, and the feet brownish yellow; a specimen described by Shaw, as *P. militaris*, is considered as a variety of this one. This species is found in various parts of South America.

Goulded Manakin (P. gutturosa) is so named from the feathers on the sides of the neck, which are long, slender, and puffy, and have the appearance of an enlargement or goitre on each side of that organ. The upper part is black, and the under part white; the bill and feet yellow, and the length three inches and a half. The female is russet on the upper part and reddish white on the under. It is described as from the northern parts of South America.

White-throated Manakin (P. gutturalis). The whole plumage of this species is glossy black, with

the exception of the throat, which is white down to the upper part of the breast; the lower mandible and the internal margin of some of the quills. The upper mandible is black, the feet red, and the length a little more than three inches. In the female, the upper parts are olive green, the under parts white; the quills and tail feathers are blackish brown, and there is a white spot over the eye. This species is also from the northern parts of South America.

Golden-breasted Manakin (P. pectoralis). Upper parts bluish black; and head, neck, and lower part of the breast, of the same colour; with a large gorget of brilliant golden yellow on the upper parts of the breast; the under parts reddish brown, the bill brownish, the feet ash colour, and the length three inches and a half. The colours of the female are not known.

Racquet-tailed Manakin (P. longicauda). This is one of the largest species, measuring five inches and a half. It is black on the upper parts, bright red on the head, passing into orange at the roots of the feathers; the quills and tail feathers margined with pale blue, the two middle feathers of the tail considerably longer than the rest, having their webs very short for some distance, and then expanding to a little oval disc on each; the chin and throat deep black, the remainder of the under part pale blue, the bill brown, and the feet reddish. The female is dull green on the upper part, mottled with green on the upper parts, and has the sides of the wings whitish.

Blue-headed Manakin (P. cyanocephala). Olive green on the upper parts, with the head and nape pale blue, and the rump yellow; the quills and tail feathers black, bordered with green; the under parts bright yellow, mottled with green on the flanks; the bill and feet black; the length three inches and a quarter.

Red Manakin (P. aureola). Black on the upper parts; brilliant red on the top of the head, the throat, and the breast; forehead and sides of the neck orange yellow; quills, with the exception of the first on each wing, marked with a white spot in the middle; under wing coverts yellowish; belly mottled with black, red, and orange; bill and feet blackish; and length three inches and a quarter. The female is olive on the upper part, and greenish yellow on the under; and she has a ring of red round the top of the head, something in the form of a little coronet. The young are entirely olive, with the front, neck, throat, breast, and vent feathers spotted with red. They do not acquire the black till they are adult. This species has been observed in Guyana; and as the young and the female are very different from the male in their plumage, and have been observed with care, we are naturally led to suppose that many of the species which have been described from a solitary specimen, are the young of others, which assume very different aspects in their mature plumage. It is important to know that any genus of birds is subject to changes of this kind, because the changes always run more or less through every species of the genus; and this ought to teach systematists a little caution as to the number of species which they establish from colour alone. In its mature plumage, this is one of the most beautiful of these birds,—beautiful as most of them are.

Green Manakin (P. stringillata). This is a Brazilian species, three inches and a quarter in length, and the female is a very handsome little bird. The upper part is of a rich green colour, and the top of the head ornamented with a fine crest of the most brilliant red. The quills are brown, bordered with

white on their inner webs; the tail feathers are very short, and of a greenish ash colour; and the under parts are yellowish white, finely pencilled with brown lines; the bill is brown, and the feet yellow. The female is entirely green on the upper part, and without the crest; and brownish yellow on the under.

Blue-backed Manakin (P. parvula). This species is found both in the West India Islands, and the tropical parts of the American Continent; and, like the last, it is a very handsome bird. Its length is four inches and a half. The plumage on the upper part of a deep velvet black, with the back and the wing coverts sky blue, and the top of the head is covered with bright red feathers, forming an erectile crest. It is subject to some varieties in colour even in the mature bird; for specimens are met with having the crest orange, and others with all the upper parts green. The female is olive on the upper part, passing into yellow on the under, and has no crest. The young male is also without the crest, and all over of a greyish olive.

Manakin.

Besides the species which we have enumerated, there are perhaps a few others which are well established, though the greater number of those we have omitted seem to be doubtful. This seems to be especially the case with some species which have been described as natives of New Holland, and others as natives of Southern Africa. We do not question the existence of the birds thus described, in either the one country or the other; but we incline to the opinion that this genus belongs entirely to America. It is an obscure genus in its general habits, and it is one of which (from the causes that we have mentioned) the species cannot be settled without a good deal of difficulty. But the established species are so many, and the birds are so generally distributed in the close and damp forests, or, more strictly speaking, on the margins of the little openings with which these are interspersed, that we must reckon them among the most characteristic of the small birds of tropical America. They are strictly tropical, both in their plumage and in their geographical distribution; and the particular character of their plumage, though pure and brilliant in its colours, points them out as being—in part, at least—vegetable feeders, and as having no predatory habit about them, farther than capturing small insects. The omnivorous birds of those latitudes, and, generally speaking, all birds which are disposed to be pugnacious with their winged neighbours, have metallic glosses and reflections in some parts of their plumage, as if they were clad in armour for the purpose of fighting. This extends even to the humming birds, which, notwithstanding their diminutive size, are exceedingly bold and pugnacious in their dispositions, and drive their needle-like bills at the

eyes of birds ten or even fifty times their own size. The dwellers in peace, again, which annoy no bird, have their plumage beautifully close and soft, but without any reflections, so that their colours appear the same in whatever direction the light falls upon them.

MANCHINEEL, is the *Hippomane mancinella* of Linnæus, a lofty West Indian tree, said to be poisonous to horses. The flowers are monœcious, and the tree ranks among the *Euphorbiaceæ*. The sap, which exudes when the boughs are cut or broken, is very acrid; it will blister and sphacelate the skin, and if inserted into wounds cause death.

MANDRAGORA (Tournefort). A genus of European herbaceous perennials, belonging to *Solanaceæ*. This is the famous mandrake of the ancients; the root is carrot-shaped and fleshy, and often forked. Fanciful people have thought that when thus divided, it bears some resemblance to the legs of a man; and the crafty have not failed to assist the folly of superstition by artfully increasing the similitude, and attributing to the plant supernatural powers.

MANETTIA (Meertia). A genus of climbing plants, natives of the West Indies; the flowers are tetrandrous, and belong to the natural order *Rubiaceæ*. Generic character: calyx of from four to eight or ten segments; corolla tubular, throat contracted, limb four-parted and hairy within; stamens inserted on the throat, and included; style simple; stigma bifid; seed-vessel of two valves, seed roundish with membranaceous margins. These plants thrive in any light soil, and are easily propagated by cuttings.

MANGIFERA (Linnæus). An East India fruit-tree belonging to *Polygama Monœcia* of sexual botany, and to the natural order *Terebinthaceæ*. Generic character: calyx of four parts; corolla of five lanceolate petals larger than the calyx; stamens one fertile, the others sterile; style filiform; stigmas headed; fruit a one-seeded drupe, flesh full of woody fibres near the nut. This is one of the best of tropical fruits, and is extensively cultivated both in the East and West Indies. By cultivation they are very much improved in quality; some of them being as free from stringiness as are our best clingstone peaches. They contain a rich yellow melting pulp, but though highly gratifying to the palate, they can hardly be compared to our best peaches. The trees have been long inmates of our stoves, and pretty good fruit have been matured both in France and England. And no doubt when the trees which we have now in cultivation attain a greater size and age, they will frequently bear fruit, especially if some pains be taken to assist impregnation.

MANGROVE, is the *Rhizophora mangle* of Linnæus. A curious Indian tree, growing on the banks of large rivers, or on the sea-coast, and even within the bounds of the ocean as far as low water mark. Their mode of rooting is peculiar: it consists, not like that of ordinary trees of divisions of the stem below the surface of the ground, but as it were of arches of roots above it, so that a more extended base is formed, and a firmer hold established in the loose and swampy soil. From the summit of these arched roots the trunk of the mangrove springs, and attains a considerable height. Another remarkable property of this tree is its habit of reproducing itself viviparously: that is, its seeds germinate and emit roots before they are shed from the capsules.

MANTICORA (Fabricius). The first genus of coleopterous insects in the system of Latreille, be-

belonging to the family *Cicindelidae*, or tiger beetles, and composed of a large species inhabiting South Africa (*M. mariloba*, *tuberculata*, De Geer), having the tarsi cylindrical, and alike in both sexes, the abdomen very large and entirely embraced by the elytra, which are soldered together, the wings not being developed; the mentum is also furnished with a central tooth. The insect is entirely of a black colour, and is found in sandy situations.

MANTIS (Linnaeus; or rather **MANTIDÆ**). A family of predaceous insects, belonging to the order *Orthoptera*, and section *Cursoria*, Latreille, distinguished by the five-jointed tarsi, the longitudinally folded under-wings; the extended prothorax, prominent head, and narrowed and elongated body; the palpi are short, and the fore legs raptorial.

The singular attitude assumed by these insects when about to seize their prey, which consists of other insects, has obtained for them the name of *mantis*, that is, soothsayer. Taking their station in a convenient situation, and remaining immovably fixed with the long prothorax elevated in the air, their fore legs being prepared to seize their prey, the mantidæ pass many hours in this position, and the superstitious inhabitants of the countries where they are found, have fancifully considered that they indicated to the passers by the road which they ought to follow, and even that they were able in some mysterious manner to predict future events. The long fore arms of the insect elevated in the form of arms, at the same time with the head and thorax, have also caused these insects to be compared to persons in the act of prayer, whence they have obtained the vulgar name of *Prigadion*, or *Prie Dieu*, in the southern parts of France and Italy, and the same idea has induced the application of such specific names as *Mantis religiosa*, *preciosa*, *sancta*, *oratoria*, &c. The names of other species, *medica*, *pauperata*, *superstitiosa*, have originated in the curious begging attitude of the insects; whence in some countries they are regarded as something sacred, and which the inhabitants consider it a duty not to harm*.

These are the only orthopterous insects which subsist upon other insects, and for this end their entire structure indicates strength and agility. The legs are long and slender, and support a long and slender body. The prothorax itself is disproportionately long in many species, but this gives a very great increase of motion to the head: the head itself is vertically attached by means of a short kind of slender neck, which permits great freedom in its rotatory motion. But the most curious part of the structure of this group of animals consists in the organisation of the fore legs, which are much stronger than the posterior legs, and are occasionally used in walking or running, but ordinarily their usage is the prehension of their food, and nothing can exhibit a more beautiful adaptation of structure to functions than is to be observed in the fore leg or hand of the mantis. The coxae are very long, and, indeed, have by some writers been regarded as the real femora, but such is not the case; the trochanter is the minute follow-

ing joint, and is succeeded by the femur, which has been sometimes considered as the tibia, and which is very robust, and armed on the inside with two rows of strong spines, between which the tibia is received when unemployed, this tibia is curved and also armed with spines along its whole inner length, and is terminated by a strong hook which folds upon the femur. At the basal part of the hook the true tarsus is attached, consisting of five slender joints, and which in no way assist in securing the prey. When, therefore, a mantis is about to seize a fly or any other insect, feeble it is true, but very active, it elevates the fore part of the body, resting upon its four hind legs, the middle pair being advanced forwards, the anterior femur is brought into contact with the coxa, and the tibia rests upon the femur; no sooner is the luckless insect sufficiently near, than the fore leg is extended to its full length, and the insect immediately seized by the tibia, which is immediately folded upon the femur, the prey being completely secured by the numerous teeth which arm both the femur and tibia, and is then leisurely devoured; should the fly escape, the mantis follows it in the most cautious manner, moving almost imperceptibly along, until it is again within reach, watching it with the same eagerness as a cat does a mouse.

Rösel has given an interesting account of the history of one of these insects in the fourth volume of his *Insecten Belustigung*, from which it appears that they are very voracious; he kept some a long time, feeding each with four or five flies per day, the females requiring as many as six, being larger. When, however, two were placed in a box together, their carnivorous instinct impelled them to violent combats, cutting at each other with their fore legs, and not ceasing until one had decapitated the other. Even when very young, they attack each other, and the male occasionally falls a victim to his unwilling partner; even after coupling the former pays the forfeit of his life, being killed and devoured by his bride: and it is even stated in the seventy-fifth volume of the *Journal de Physique de Rozier*, that an instance had been observed, in which the female had first cut off the head of her mate, coupling had afterwards taken place, and the male was subsequently devoured by the female. The Chinese, aware of this fighting propensity, keep these insects in little bamboo cages, and match them together in combat, as is done in this country with fighting cocks.

After impregnation, the female takes her station on the twig of a plant, and remains there several hours, without any other motion than a very slow progression, during which the eggs are deposited, and are covered with a soft and whitish substance, forming a large mass, which may be easily mistaken for a fruit, and of which the form varies in the different species, the substance soon hardening, and gaining a yellowish colour. The eggs are arranged in regular series, out of one end of which the young make their escape at the expiration of nine months after the deposition of the eggs, which takes place in September, the young not being produced until the following June. The young larvae have all the appearance of their parents, but are destitute of wings and wing covers. Rösel, indeed, having opened an egg previous to the bursting forth of the larvæ, mistook for a pupa the little creature therein contained, although at the same time he was acquainted with the state which was really analogous to the pupa, and in which the wings and wing covers are very short and rudimentary.

* "So divine a creature is this esteemed," says old Monnet, "that if a child asks the way to such a place, she will stretch out one of her feet and show him the right way, and seldom or never misse. As she resembleth those diviners in the elevation of her hands, so also in likeness of motion: for they do not sport themselves as others do, nor leap nor play, but walking softly she returns her modestly, and shewes forth a kind of nature gravity."

mental, as in the grasshoppers. The larvæ change their skins several times, but arrive at the imago state in about three months.

The *Mantidæ* are found in situations exposed to the hottest sun, appearing most active in the greatest heat. In the South of France they are much more inactive towards November, and may then easily be caught. At all times, however, it is difficult to escape being wounded by the acute spines of their fore legs, which readily pierce the skin. In some species, indeed, the fore legs are nearly destitute of these spines, and of a short size; they must, therefore, be less carnivorous than the others, conducting naturally to the following family, *Phasmidæ*, in which the fore legs are of the ordinary structure. Some species, forming the genus *Eremiophila*, first discovered by Savigny, and more recently by M. Lefebvre, in the desert plains of Egypt, where insects are rarely to be met with, are nevertheless powerfully armed. And hence it has been conjectured that these insects must possess the power of sustaining a long fast. Their movements, moreover, are very slow; but they differ from the other *Mantidæ* in the colour of the body, which resembles that of sand, upon which they are found. Hence, perhaps, we may attribute to them the possession of a deceptive art in procuring food, of which we have given other instances in our general article, INSECT.

Mantis.

These interesting insects are extremely numerous in species, inhabiting the warmer districts of the earth, and reaching as far north as the middle of France. None, however, have been found in this country. They are extremely variable in their forms. The antennæ in general are short and simple, but they sometimes acquire a great length, and in the males of some species they are beautifully pectinated. The head itself in some species is ornamented with an elevated tubercle, supporting a leaf-like appendage. The ocelli are three in number; the eyes large, globular, and lateral; the prothorax is sometimes furnished with flattened wing-like appendages at the sides, varying in size, and sometimes giving this part of the body a remarkable appearance. The four hind legs are generally single, but in others the femora are furnished near the tips with leaf-like appendages. The wing covers are also very variable in form, and the abdomen is furnished at the extremity with two conical articulated filaments, as in the *Blattidæ*. The males do not appear to be provided with the two

short threads between the preceding, which are found in the male *Blattæ*, but this sex may be easily distinguished by the number of abdominal segments, of which there are eight in the males, and only six in the females, on the ventral part; whereas there appear to be nine dorsal segments in both sexes. The females are also easily distinguished by the large size of the terminal segment of the body, which is preceded by equal sized segments; whereas the terminal segment in the male is very small, the preceding being very short. Latreille united all these insects into a single genus *Mantis*. M. Serville, however, in his classification of the *Orthoptera*, published in the *Annales des Sciences Naturelles*, proposed numerous genera founded upon various structural peculiarities, which it is unnecessary to dilate upon in a work like the present, having already noticed the most material modifications to which these insects are subject. M. Lefebvre has also added some other genera in his memoir upon the *Eremiophila*, published in the "*Annales*" of the Entomological Society of France.

MAPLE is the *acer* of botanists, so called from the sharpness of their juices. There are many species, either shrubs or trees; four of them are British, common in hedges. This genus gives a title to one of the natural orders, namely *Acerineæ*.

MARANTA (Linnaeus). A genus of reed-like plants found in the warm parts of America, belonging to the natural order *Cannææ*. They are nearly allied to ginger, but the pungent aromatic principle is wanting. The tubers contain much fecula, which is collected and prepared as food; and, from its former use as a cataplasm for arrow-wounds, it is commonly known under the name of arrow-root. This farinaceous substance is procured from many different species, but chiefly from *M. arundinacea*, in the West, and from *M. alouya* and *ramosissima*, in the East Indies. In our stoves they grow well in light, rich soil, and are increased by dividing the roots.

MARCGRAVIACEÆ. A small natural order of plants, containing four genera and six species. The genera are *Antholoma*, *Marcgravia*, *Norantea*, and *Ruychia*. They are all very curious half-climbing shrubs, or small trees, with pitcher or hood-shaped bractæ, something resembling the vessels formed by the metamorphosed leaves and leaf-stalks of *Cephalotus* and *Nepenthes*. Of the properties of these plants there is at present nothing known, and even their station in the system is debatable. There are two suborders, namely, *Marcgraviaceæ* and *Noranteæ*. In the former, the corolla is calyptriform; while in the latter the five petals are free.

MARMOT (*Arctomys*, literally "bear rat," or rat having the body formed something like that of a bear). Under the article *Arctomys*, in its place in the alphabet, there will be found a few remarks on the general characters and habits of this genus of *rodentia*, and a reference to the present article for the species, the chief of which we shall now enumerate as briefly as possible; but, it may not be amiss to mention the generic characters in brief, because the genus consists of two sections; or rather, it is a family or group, consisting of two genera, which differ considerably in their structure. The characters are two very strong incisive teeth in each jaw, rounded on their anterior surfaces; no canines in either jaw; five cheek teeth on each side of the upper, and four on each side of the under, with their crowns furnished with ridges, and also with tubercu-

less points; the body thick and heavy; the head and eyes of large dimensions, but the ears small; the feet very strong, with five toes on the hind ones, and four, together with a rudimental thumb, on the fore. The claws upon all very stout and compressed, but better adapted for digging than for prehension, though all the animals have clavicles, and can bring the fore feet to the mouth. The two sub-divisions, or subgenera, which have been established by M. F. Cuvier, are chiefly founded upon the absence or the presence of cheek pouches: but, in the greater number at least, there is another important character which accompanies this; those which are without cheek pouches are social, living in considerable numbers, often several families in the same burrow; and those which have cheek pouches are solitary, living singly or, at most, in pairs. The old generic name, *Arctomys*, has been restricted to the social species without cheek pouches, of which the Marmot of the Alps is the type; and the solitary division, with cheek pouches, of which the Souslik, or Siberian Marmot, is the type, has received the name of *Spermophilus*. We shall take the enumeration of the species under these names, for the sake both of perspicuity and brevity, though there are some of the imperfectly known species which it is difficult to arrange.

ARCTOMYS. The chief distinction of these having been mentioned just above, there is no necessity for repeating it.

The *Marmot of the Alps* (*A. marmota*) inhabits, as its name implies, the Alps, and some of the other lofty mountains of Europe; but it is not found even in the most mountainous parts of the British Islands. It is an animal rather more than a foot long from the nose to the root of the tail; its colour is subject to some variation; but the prevailing colour on the upper part is dark grey, with the tip of the tail black. The feet whitish, the part surrounding the muzzle whitish grey, and the under part of the body bright brownish red. Its large head, its clumsy body, and its short thick legs, give it what one would be apt to consider an expression of stupidity; but in the case of no animal is the external appearance more at variance with the facts. In a state of nature it conducts the making of its burrow with greater neatness, and keeps it in better order than any of the burrowing rodentia, and its domestic economy is scarcely inferior to that of the beaver itself. In fact, though the hut of the beaver is a structure reared, and the burrow of the marmot is excavated, there is an ingenuity in the one burrow which is not found in the other. It always consists of two galleries, the one of which contains the dwelling and the entrance to the dwelling; and the other, which meets this, but has a greater inclination and opens farther down the slope, and at a lateral distance, is a sewer or drain, by means of which the inhabited portion is always kept dry and comfortable. The nest consists of a great quantity of dried grass and moss, and is made sufficiently large for holding a considerable number of the animals, which keep one another warm during the inclement season, which is often very severe in the elevated places which these animals inhabit. All the society which inhabit the same burrow work in concert, both in preparing it and stocking it with those provisions which are necessary before they pass into a dormant state for the winter, and after they awake in the spring, and before the fields are fit for their support. It is very generally said, that in carrying home their stores, one

of the society allows the others, and even invites them, to use his body as a sort of sledge. He turns on his back, and is loaded with as much of the dry grass, or moss, or other necessary of a marmot's life, as he can hold together with his paws. When he is thus loaded his comrades seize him by the tail and pull him along with his load, he contriving to keep steadily on his back all the time. As those which act horses to this singular sledge get tired, they are relieved by others; and if "sledge" himself gets exhausted, another is loaded, and so on until the load is safely conveyed to the burrow. There are many other little particulars in their domestic management, contributing to comfort or to cleanliness, the detail of which would render this article too long.

The marmot of the Alps is easily tamed; and in a domestic state it is a very docile, gentle, and intelligent creature, and may be taught many little tricks, all of which are amusing, and none of them offensive. It is not so productive as some of the other rodentia, there being only one litter in the year, each litter consisting in general of about five; but the animals are subject to fewer casualties than one would suppose, in the cold places which they inhabit, and where the keen eyes of eagles and vultures and other powerful birds of prey may be supposed to be frequently upon them. They are very vigilant creatures, however; and it is understood that when they are engaged in their labours, they always have a sentinel posted on some rock or other eminence, who keeps careful watch, gives notice of danger before it is near, and has himself some little place into which he can retire and remain till the danger is over.

The *Polish Marmot*, or *Bobac* (*A. hobac*) is nearly of the same size with the former, but is a little different in the colour. The general colour is yellowish grey, mottled with brownish black, with the under part of the body yellowish russet, and the throat and tail reddish. A portion round the eyes is brown; and that round the muzzle is silver grey. Its native localities are further to the north than those of the marmot of the Alps; for it is found from Poland to Kamtschatka. It does not inhabit such elevated places, however, as the Alpine marmot; and therefore, though it is found in higher latitudes, it does not follow that it is in a colder climate. It is also careful in selecting the exposure of the situation in which it forms its burrow, and also in the kind of soil in which it is made. It always builds or burrows in a bank sloping to the south, and in dry soil. The burrow is deep, and lodges a colony of from twenty to thirty individuals. The quantity of dried grass introduced into these social burrows is very great; and they are equally industrious in their labours.

The *Maryland Marmot* (*A. monax*) is an American species, belonging to the same division as the two European ones which have been mentioned, and nearly of the same size. It does not inhabit the very cold places of America, but rather the central and southern parts of the United States, and perhaps places further to the south; for Catesby styles it "the Bahama rabbit." In the United States it is called the ground hog, and various other local names, none of which are very applicable. Its colour is rusty brown, rather darker on the flanks than on the middle of the back; a portion round the muzzle is bluish grey, and the tail is black.

The *Quebec Marmot* (*A. empetra*) is not the Canada marmot of Buffon, though it is that of some of the

later and more accurate French naturalists. Buffon's Canada marmot is the Carolina one last mentioned, which, instead of being found in Canada, does not reach the northern, or even beyond the central part of the United States. This is of a blackish brown, mottled with white in some places. The top of the head is a uniform brown, passing into reddish brown on the nape. The cheeks and chin are whitish grey; the breast and paws bright red; and the tail, which is short but covered with abundance of hair, is black. It inhabits very cold countries, being found in great numbers in the environs of Hudson's Bay, where, of course, it passes a considerable portion of the year in a dormant state. Though it is the American species which has been longest known, there have been some mistakes besides that of Buffon, to which we have alluded. The marmots, and the smaller ground mammalia of North America generally, to whatever order they belong, form a department of the history of mammalia upon which information is still very much wanted. The country is so very wide, so well adapted for animals of this description, and many parts of it are so difficult to be explored during the summer, in consequence of floods and quagmires, that there may be many animals of this description, especially hibernating ones, of which we may be still ignorant.

The *Missouri Marmot* (*A. missouriensis*) inhabits the dry plains on the western side of the great central valley of North America, extending southwards toward Louisiana, in many places of which it is exceedingly abundant. Its general colour is reddish brown, with a large head flattened on the under part, the eyes very large, with the irides of a dull brown colour; but the ears so short, that they appear as if they had been shortened by art. The cheeks and a portion over the eyes are furnished with long hairs; and the whiskers of moderate length and of a black colour. All the feet have five toes, furnished with long black claws; and the feet themselves are covered with very short fur. These animals are so abundant in some parts of the valley, that their burrows extend over a surface several miles in circumference. Their cry, which is loud and peculiar, has procured them the local name of 'prairie dogs'; the last part of which name is, of course, absurd; but they are strictly enough prairie animals, being found only in the dry plains to which this name is given, and never upon the humid savannahs, which would not of course suit their burrowing habits.

The *Short-tailed Marmot* (*A. brachyura*) has the social habits of the last mentioned one, and inhabits nearly the same places, only it appears to extend westward as far as the prairies on the banks of the Columbia river, and perhaps as far southward as Upper California and the Texas, if not further. It is generally speaking of a brown colour, mottled with reddish grey on the upper part, with a tail only one seventh part of the whole length. Reddish brown on the upper part, iron grey on the under, and marked with white along the sides intermediate between those colours.

The *Red Marmot* (*A. rufa*) is a species but imperfectly known, and understood to have its habitat in the dry bushy plains by the banks of the Columbia, and other places further to the west. It is described as having the fur all over of a reddish brown, with the ears very small, and covered with reddish brown fur.

Another species, the *Barking marmot*, (*A. latrans*) has been described as living in a social state in the same localities which are assigned to the Missouri marmot. Its colours are nearly the same with the latter, and its feet have the same structure, namely, five perfect toes upon each. The probability therefore is, that it is identically the same animal described from a specimen accidentally a little redder on the back than they are generally seen. This probability amounts almost, if not altogether, to a certainty, when we bear in mind that the sound of the Missouri marmot is considered in the places where it inhabits as so much resembling barking, that the animal is called the prairie dog.

The species of the social marmots of America require to be examined with a good deal of care. Many of them have been founded upon single specimens, some of them obtained from the Indians, and perhaps have been judged of without the requisite degree of attention to their structure. Now social animals require fully more care in this way than solitary ones. Living in the society of each other is the intermediate step between living solitary in wild nature and being domesticated; and therefore we might be prepared to expect among these social animals, a little of that breaking down of the uniform colour which is so common among domesticated ones. Besides this, the social ones are generally far more numerous than the solitary; and we may conclude that the probability of breaking down into differences of colour shall increase with an increase of numbers, though not necessarily at the same rate. We want information indeed respecting many of the animals of the Rocky Mountains; and it is not impossible that, in a country so extended, and so varied both in its surface and its climate, many may be discovered in future, of which we at present know nothing. It is true that the great Bonassus, which was several years ago exhibited in Britain, as an undescribed marvel from that part of America, was an unprincipled hoax, for the purpose of raising money by its exhibition; but it by no means follows that respectable naturalists, or respectable travellers of any class, could be guilty of anything of this description.

SERMOPHILUS. We have already mentioned the leading characters, both of structure and habit, which distinguish this genus of the group from the true marmots, namely, the possession of cheek pouches, and being solitary, not social. There are, however, a few other characters, which are worthy of notice, as pointing out more clearly the proper place of this genus in the order of rodent animals, which is that of a connecting link between that of the true marmots and the ground squirrels. The most remarkable of these are the feet and legs more lengthened, the feet longer, and all free, with a single tubercle at the base of each, not covered with hair. The most remarkable difference, however, is in the bones of the head, the oval pupils of the eyes, and the perfectly free toes.

The *Siberian Marmot*, the *Souslik*, or *Zizel*, (*S. citellus*), is the typical genus. It is of a yellowish brown colour on the upper part, varied, and spotted with transverse markings of white, and has the under part entirely white. The cheek pouches are large for the size of the animal. It is by much the most handsome of all the marmot group or family; and when it was considered as a regular member of that group, it was considered as the variegated marmot. There are,

however, one or two coloured varieties, one spotted, another waved, (which is the one to which the name *zibel* is more immediately applied,) and a third one is of a uniform yellowish brown. This species is understood to be considerably more carnivorous than the true marmots; for, along with its hoards of seeds and small fruits, the bodies of little quadrupeds are met with. The name Siberian marmot is not very correctly applied to it, inasmuch as it occurs in longitude from Bohemia and some other parts of Germany, eastward to the shores of the Pacific, and southward to Persia and India.

Parry's Marmot (*S. Parryi*) is an American species, belonging to the same genus, and is found in the extreme north of the American continent, having been noticed by Hearne on his journey, and it was considered by him as a ground squirrel. Richardson observed it again on Franklin's expedition, and assigned it its true place in the system. It has the fore paws with five toes on each, the external ears exceedingly small, and the tail long, and black at the extremity. The upper part of its body is mottled with black and white, and the under part is rusty red. It is furnished with cheek pouches; but though we may conclude from its structure that its habits do not differ greatly from the species last described, it has not been observed with sufficient minuteness for enabling us to state positively anything respecting its habits.

Franklin's Marmot, (*S. Franklini*.) This species is known in its native country by the name of the grey marmot of America. The hair on the upper part of the body is short, and barbed or annulated with a number of colours, consisting of blackish, sandy white, black and white, yellow and blackish, blended together on different parts of the hairs. The hairs on the under part are blackish at the roots, and sandy white at the points; and those on the tail are annulated in a similar manner. These different colours of the single hairs of the covering give the animal a greyish appearance, with the exception of the long hairs above and below the eyes, and the *montachios*, which are black.

Richardson's Marmot (*S. Richardsoni*) is another native of the far northern parts of America, which is locally known by the name of the tawny marmot. The top of the head is covered with short hairs, which are black at the base and brighter coloured at the points. The muzzle and cheeks are brownish, and the brown hairs mixed partially with the blackish ones on the top of the head. The throat is sandy white. The upper part of the body is covered with soft fur, blackish at the base and yellow at the points, which gives it the tawny appearance from which it obtains its local name; but the middle of the back is of nearly the same colour as the top of the head. The flanks are greyish brown; and all the under part reddish brown. The tail is covered thinly with long hairs, which are annulated with different colours. The external ears are oval and short. The inner toe on the fore foot is very small, and has a short blunt claw; the toes on the other feet, both before and behind, are well developed, with horn-coloured claws, very sharp and crooked. It is presumed that this species partakes a good deal of the carnivorous character; but both its manners and its habitation are very imperfectly known.

The *Powdered Marmot* (*S. pruinosa*) is another North American species, about the size of a

rabbit. The point of the nose is black; the ears short and oval; the covering on the upper part formed of hairs annulated with three different colours—ash-coloured at the roots, black in the middle of the length, and white at their extremities, which gives the animal the appearance of being dark grey, powdered over with whitish. The tail is a mixture of black and red, and the cheeks are whitish.

These species are probably not the only ones in the extreme north of America; and as the species of the eastern continent is known to break into differently coloured varieties in places which differ in their physical characters, it is by no means improbable that the American ones may do the same; and that some of those which have been described and named as different species, may be only accidental varieties of the same.

All the animals of this genus are more nocturnal in their habits than the true marmots; and from this, and their living solitary and in wild places, their manners are not so easily studied; neither is it easy to come to a just conclusion as to what is a species and what is not. Social animals can always be studied with comparative ease; because their social habits make them less afraid of man than the solitary ones are; and there is the advantage of seeing numbers of them together, which is always a certain means of establishing species, and ascertaining habits in a more satisfactory manner, than when only one species can be seen at a time. Altogether the marmot group, both in the true marmots and in the allied genus of which we have now given an outline, are interesting animals, from their peculiar habits, and also from the place which they occupy in the classification.

MARSDENIA (R. Brown). A genus of very fragrant under-shrubs, natives of Syria and New South Wales. They belong to the fifth class of Linnæan botany, and to the natural order *Aclepiadaceæ*. They are easily managed greenhouse plants.

MARSH CINQUEFOIL is the *Comarum palustre* of Linnæus, a common British bog plant belonging to *Rosaceæ*.

MARSH MALLOW is the *Althæa officinalis* of Linnæus, a British plant formerly famous for its medicinal qualities. It belongs to *Malvaceæ*, and is most frequently met with on salt marshes.

MARSH MARIGOLD is the *Caltha palustris* of Linnæus, a very conspicuous British plant frequently seen in damp meadows. It belongs to *Ranunculaceæ*. A double variety of it is cultivated in flower-gardens.

MARSUPIALIA. Mammalia which have a double gestation, and, generally speaking, an abdominal marsupium or pouch for receiving the young. See **MAMMALIA**.

MARTEN (*Mustela*). An extensive genus of digitigrade mammalia, first established by Linnæus, but considered as a sort of sub-tribe or section by Cuvier, and by him arranged into four genera. An account of the last of these in Cuvier's order, the otter, will be found under the title *Lutra* in its place in the alphabet; and therefore the details of this article will be restricted to the other three. There is some advantage in thus separating the otters from the rest; because though in their general structure they agree with the others, and are equally carnivorous, yet they have webbed feet adapted for swimming and feed upon fish, while the rest of the section, in all the three genera, feed chiefly, and many of them

exclusively, on warm-blooded animals; and their cheek teeth are of a more bruising and tearing character than those of the otters.

Martens of every genus have six incisive teeth, two canine, and two carnivorous, and two tuberculous teeth in each jaw; but the number of their false molars is subject to some variations, which are attended with differences in the general character and habits of the animals, and for this reason they are worthy of attention. Many species have six above and eight below, and others have only six both ways, so that the total number of teeth varies from thirty-eight to thirty-four. These variations in the number are not, however, of very primary importance, because it is the form of the teeth which is our best guide to the food and feeding of any of them, and the number is rather a secondary matter. The additional four teeth which occur in many of these animals are never so fully developed as the rest, and they are sometimes little more than rudimental. Their establishment in the jaw is less firm, as they have only one fang or root, while all the others have two or more: they are also less efficient in their crowns, which consist of a single smooth and blunt point. The other false molars, which are more firmly established in the jaw, are narrow from the outside to the inside, broad from the front to the rear, and very sharp in the points. The carnivorous teeth which come behind these very much resemble those of the cats, which are the most carnivorous of all animals; and thus the martens have a very strong carnivorous character in this particular tooth. The upper one has an internal tubercle which is very distinct; and the lower one has a heel or projection on the back part, which decreases its cutting and tearing character. The tuberculous teeth in the lower jaw are small, rounded, and have their crowns formed into three points. The upper ones are much larger, especially from the front to the rear; and they have a furrow in the length of their crowns, irregular in its depth, and well calculated for acting against the irregularities of the lower teeth in bruising flesh in its recent and tough state. The whole mouth indeed is of a highly carnivorous character.

The legs of the whole are short, and the foot always consists of five toes, which are united by membrane for a great part of the length. The inner toe is the shortest of the whole in all the family, and the middle and fourth ones are usually the longest. The remaining two, though shorter than these, are both of equal length. The balls of the toes are furnished with naked tubercles of an oval form, and there is another in the middle of that part of the foot which comes to the ground in walking, and this middle one has three lobes directed toward the toes. The foot is thus both a firm one and one not liable to be injured, though planted with force upon hard and rough surfaces; and thus the animals can bound and leap after their prey with great agility, in which they are further assisted by the length and elasticity of the spine. The claws of all, with the exception of the *zorilla*, or polecat of the Cape, afterwards to be noticed, are crooked as well as very sharp in the points, though they are in no species decidedly retractile like those of the cats. Most of the species can, however, climb walls and trees, and get over lofty obstacles and through small openings, with very great facility.

The body is, in all the species, long and slender, and, though elastic and capable of being made very

stiff by muscular exertion, it can also move more lithely than that of most other mammalia. The covering is soft and fine in all the species; and it consists of two kinds of fur, the one longer, silky, and glistening, the other short and woolly, and remarkably close. In most of the species the skin is very firm, and both kinds of fur stick firmly to it; and if we except that of some animals which live habitually in the water, the skin and fur of the marten tribe are less liable to be injured by the weather than those of any other small animals.

On this account the skins of many of them are sought after with great avidity as furs, on account of their warmth, their beauty, and their durability jointly; and though the skins of various other animals are used as furs, those of the marten tribe are most valued, and they themselves considered the fur animals by way of eminence. In one or other of the species they occur in almost every part of the world, with the exception of Australia and some of the remote islands; but the regions of the north, close by the shores of the polar ocean, are especially their head quarters; and it is there that the finest furs are obtained, and they are obtained in immense numbers both in the Eastern continent and in America.

None of the martens pass the winter, or any part of it, in a state of lethargy, even in the coldest places which they inhabit. They are animals of too much energy for this; for, though many of the hibernating mammalia can make considerable exertions during the season of warmth and activity, there is always a trace of something sluggish about them. The martens, on the other hand, are so full of energy and life, and so strong in proportion to their weight, that it is exceedingly difficult to fatigue them; and, what is not universal among animals, they are as tenacious of life as they are energetic in the exercise of it.

Protected as they are by their double covering of fur, they are nearly indifferent both to changes of temperature and changes of the weather. They do not pant in the summer's heat, neither do they shiver in the winter's cold. Rain, or immersion in water if that be necessary, does not readily wet their living fur, and snow makes comparatively little impression upon them. The long silky portion of their fur throws off rain or snow like a nicely adapted thatch: while the woolly part among the roots is so fine in the staple, that it is perhaps one of the best non-conductors of heat in nature, and the very best among the mammalia.

Any one who reflects upon the great advantage which his own body receives from as near a uniformity of temperature as he can command from artificial clothing, must readily convince himself of the great saving of the energy of an animal which must be effected by this means. There is nothing which so soon wears out the system by natural decay, and nothing which so frequently exposes it to disease as alternate heating and cooling; and if we compare one of those fur animals clothed in its non-conductor, with a tropical animal in its thinly-scattered covering of coarse hair, which admits a full play of the temperature against the skin, we shall readily see that those animals can bear, without the slightest inconvenience, extremes of heat and cold, which would very speedily destroy the tropical animal, by actually wearing it out beyond all possibility of exertion.

There is therefore not a more beautiful instance of adaptation of animal and country to each other, than

that of the marten tribe to the extreme north of the continents. Owing to geographical causes which it would be foreign to our purpose to explain, the summer there is, taking the whole twenty-four hours, and referring to places where it rains but seldom at that season, warmer than any spot under the equator; while in the winter the cold is so intense that mercury remains solid for weeks or even for months.

The high average temperature of the summer in those polar latitudes arises from the perpetual presence of the sun, which, after a time, brings the dry surface of the earth to a degree of heat unknown in the temperate or even in the tropical latitudes. In the latter, the direct action of the sun is no doubt greater, but it lasts on the average only twelve hours out of the twenty-four; and during the remaining twelve, the earth is greatly cooled by the radiation of heat from it through a cloudless sky, and the evaporation of the heavy dew which is constantly forming on the surface, and as constantly dissolving or evaporating by the heat which radiates from beneath. The tropical animal has therefore a refreshing pause of nearly half the four-and-twenty hours from the ardour of the climate; and beasts of prey, which are from the nature of their food the most laborious of all animals in a state of nature, are adapted to this state of things. They retire to their dens before the heat of the day comes on, remain there till the evening, and begin to stir themselves only after the shades of night have gathered around. They are, almost without exception, very noisy animals, and nature has so adapted them and their prey to each other that their voices strike terror, and cause the prey to discover itself by its efforts to escape. The martens and other predatory animals of the cold countries need no such repose, and require no such noise. They beat about; and though they too, in seasons when there is night, prey more by night than by day, yet they do not loiter a part of their time like the others, but are always on the alert, and always ready for action; and one knows not which most to admire, the excellence of their defence against the great variations of season to which they are exposed, or the economy of animal action which is produced by this species of defence.

But though these animals, fitted for making their way through very small openings, and treading very softly from the lightness of their bodies and the peculiarities of their motions, can come upon their prey silently and without the sound and fury which accompany the spring of a lion or a tiger, are yet furnished with means by which their coming is known; and thus where the animals on which they prey have free scope for making their escape, the number which they can capture at a time is limited to one. When a polecat for instance invades the farm-yard or the hen-roost, where the birds are confined, it kills one after another; but in free nature, if it succeeds in seizing one, all the rest are gone, the offensive odour of the animal giving them sufficient intimation of its presence. All the rest have not the same offensive smell; but few of them have an agreeable one; and in some it is so superlatively disgusting that no living creature can remain and breathe within a considerable distance of them. This odour is secreted by small glands on the posterior part of the body; and there is no doubt that it serves the double purpose of protecting from them the animals on which they prey, and protecting them from more powerful animals.

The odour of our common polecat is offensive enough, but it is nothing to that of the South American animals of the family, which smell so intolerably that one dares not approach them. It cannot be supposed that this, which, though it wounds not, may truly be called an "offensive" weapon, has been given to these animals for the mere purpose of warning of their danger the weaker ones upon which they feed. In South America, when the chinche is in quest of its prey, the jaguar and the puma are also prowling about, and if it smelled even tolerably they would have no objection to make a meal of it. The odour which it gives out is, however, a sufficient defence against any animal whatever; and thus it is left to pursue its own prey undisturbed by its more powerful neighbours. It is evident indeed that the chief use of the offensive odour of these animals, in their economy, is protection against those carnivora which are more powerful than themselves; and in proportion as their habits lead them to come more in contact with these, we always find them the more abundantly furnished with this means of repelling. The polecat, for instance, which comes on the cultivated grounds, and is exposed to danger from domestic dogs, is far more offensive in its odour than the marten which keeps in the loneliness of the forest, where there are few mammalia more powerful than itself.

It is upon the rodentia chiefly, and upon birds, that the animals of this group levy their contributions; and accordingly we find that where the one are found in greatest numbers the others are found in greatest numbers also. In such a country as Britain, where squirrels and other rodentia inhabiting trees are rare, and not natives, but are introduced animals in the few places where they do occur, the staple food of the marten tribe consists of those members of the rat family which abound in the woods, though to these they often add birds. The polecats and weasels, which frequent the champaign countries rather than the forests, do occasionally capture a hare, and still more frequently a rabbit; but still the smaller rodentia are their principal food, and we have evidence of this in one weasel being more serviceable in a farm-yard for mousing than half a dozen cats. But though the members of the family or section which are found native in such countries as Britain are very interesting animals, and in their way highly useful to man, they form but a slight feature in the natural history of the country. It seems almost a contradiction, and even an absurdity in language, but notwithstanding it is true, that the natural history of Britain, or of any country so much cultivated as Britain, can hardly be called a *natural* history. It is an *artificial* history, although the subjects of it may be growth and life; and man, by extending his dominion completely over the greater part of the surface, has come instead of those predatory mammalia, and predatory animals of other classes, which but for man would have been the regulators of life. The bones of the hyæna are buried deep in the soil; the wolf has been extinct even in the wildest parts of the country for nearly a century and a half; the wild cat is confined within far narrower limits than it once occupied; sportsmen are in many parts of the country obliged to preserve foxes in order that they may hunt them; and martens are rare, and confined to very peculiar localities.

We can therefore draw no inference as to the state of wild nature, or the use of any kind of animal, from what we see around us at home; further than

this, that the predatory animal which has remained among the cultivated fields or near the farm-house, however offensive it may be, or however much persecuted, is not without its use there. As cultivation extends, and farinaceous seeds are grown in greater abundance, so the members of the rat family, whether of the house or of the field, which feed chiefly upon such substances, multiply in proportion. In the field man is defenceless against them: they are small, and are in concealment during the day, and therefore he can no more get rid of them by any device of his own, than a cultivator of fruits could get rid of caterpillars without the labours of the summer birds.

Those small rodentia to which we have alluded as feeding chiefly upon farinaceous seeds, multiply with extreme rapidity; and were it not for the weasels and polecats, the depredations which they would commit would be beyond anything which, in the present state of the country, we could readily suppose. It is true that the owl and the kite, and even the crow, come in for a share of the merit of this protection, nor must we forget the wild cat which lingers in some of the cultivated districts, and always most abundantly in those where slovenly kept hedges, and ill-dressed ditches, and idle commons overrun with breaks, afford cover for the small field rodentia. But still the weasel can follow them and find them in situations where they are perfectly safe from all the rest; and therefore it would cost a farmer more arithmetic than the majority of farmers are masters of, to sum up how much corn the weasel and the polecat save him in the course of the year.

But if such be the case in our own country, which is in a great measure taken from under the ordinary laws of nature, and brought under the regulation and controul of human art, how great must be the necessity for the animals of this family, and how much their value, in those extensive regions of the world which are still completely under the laws of wild nature! It is not in the tropical parts of the world that animals such as the members of the marten family are especially required; for there the grand spoilers of vegetation are of insect race; for from the perennial summer of tropical climates, insects of all kinds, or at least of some kind or other, are in activity there throughout the year. The animals therefore which play the same part in such climates, are insectivorous—the ant-eaters, and the various races of ant-eating lizards, the whole tribe of the edentata in short, with the exception of the few herbivorous ones, whether they carry on their operations above ground or below.

But in polar countries the case is very different. There the winter sets in early, and before its approach the parent insects all vanish, while the embryo generations for the succeeding year are quiescent in their places of concealment, and not accessible to any preying animal, at least to any of the mammalia. In those countries, however, the exuberant vegetation of the ardent summer (for summer is ardent when it comes) requires some controlling power, and this controlling power is given to a vast number of rodent animals—squirrels, rats, and mice in countless multitudes. Some of these hibernate during the severity of the winter months, and others do not; but even those which hibernate are abroad for some time after the leaf has fallen in the autumn, and again in the spring before there is a single leaf to spare;

whilst such as do not hibernate, are active in feeding throughout the winter. When there are no leaves, such animals, as a matter of necessity, have recourse to buds and bark, the destruction of which is far more injurious to vegetation than the consumption of leaves during the season of growth; and as nature is never without a counterbalancing power, something is required to regulate their numbers.

It must not be supposed that there is anything imperfect in this, for herein lies the very perfection and beauty in the system of nature. If each race could maintain itself without any other race, then the whole would necessarily be reduced to a state of perfect inaction, and the world would be no living world. But the whole are so adapted to each other as that the portion which what we call the spoiler consumes, is really as necessary to the preservation of the race of the consumed party as it is individually to the consumer; and the powers of life are so vigorous in every race, that what is necessary for the other race can well be spared.

The rodent animals in the forests of cold and tropical countries, are subject to many contingencies from the severity of the winter, besides the direct and extensive consumption of them by the animals whose use in nature we are endeavouring to point out; and as they also have their use in restraining the exuberant vegetation of the summer (which, if allowed to go on, would run everything up to stem and leaf without flower or seed), and also in consuming the surplus seeds (which in most plants are at least a hundred fold what is necessary for the succession)—as there are these necessities for the rodent animals, in order to preserve a temperate and healthy state of vegetation, and as the rodent animals are subject to the contingencies and direct spoliations which we have mentioned, the uniform law of the system requires that they should be endowed with a fecundity equal to or greater than those means which tend to thin their numbers. We know that this is the case with all the tribes of ground rodentia which are found in our own country; and we all may have read, if so inclined, of the perfect floods which are sometimes poured from the wild forests upon the cultivated parts of northern and polar countries; as, for instance, of the invasion of lemmings which sometimes takes place in Norway, and by which the surface vegetation is as completely destroyed as it is by the locusts in climates nearer the sun.

This great power of production is necessarily attended with a corresponding strength in the controlling power; and accordingly we find that in Siberia, in the northern parts of America, and, in short, round the whole polar zone, the rodent animals, and the marten tribe which prey upon them, exist in multitudes which no man can number; multitudes which, though hundreds of thousands of both kinds of animals are every winter killed by the hunters for the sake of their skins, do not appear perceptibly diminished. In this way employment is given to a vast number of people in latitudes where, and at a season when, other occupation for man in the same localities there would be none; and thus we find that in the natural economy of the polar regions, and in the severity of the polar winter, there is provision made for calling forth the skill and industry of human beings, and crowning them with an ample reward.

Nor are the trophies of the thousands of slain which are the produce of this labour without their

use in the grand commerce and accommodation of the world. It may be said that the furs of Siberia and Canada are "luxuries." But we ask, what is meant by a luxury, if the thing alluded to contributes to human enjoyment, and the possessor can afford it? If these two conditions are involved in it, everything is a necessary of life, and sable and ermine are just as much so to one who can afford them, as rags are to a beggar, or as the wool on its own back is to a sheep. It is often thought, and not unfrequently said, that the possession of such misnamed luxuries as those to which we are alluding, produces envy and discontent in all who cannot afford them, and tempts many to endeavour to obtain them by improper means. This, however, is the vice of the parties, and not the fault of the things complained of. There is an honest way of getting at them, and that is "to win them," and there is or ought to be the greater struggle for improvement, in proportion as there is more to be won. The fable, and though it is a fable it has a moral, says that the mighty Macedonian sat him down and cried when the world was won; but it will be remembered that he was bold, and venturesome, and cheerful, during the winning of it. The moral of this fable is, that while there is anything to be won we ought never to abate our cheerfulness, or slacken the hand of our industry; and really, in the natural view of the case, the man who has least has the vantage ground in this respect.

We have thus endeavoured to show not only that the martens have a use and an important use in nature, proportionate to their numbers and to their general distribution over the earth; but that they are valuable to man in many respects. Some races which will not quit, but rather which come and multiply, in proportion as man cultivates, are useful in the direct preservation of his property from enemies against which he himself has no defence. Others again find employment and furnish wealth, and the wealth so furnished, if contemplated in the proper spirit, ought, as all wealth ought, to be converted into a stimulus to intelligence and industry in those who possess it not.

This is the most important light in which we can view any production of nature, and consequently it is the light in which we ought to view it, and if we do not view it in this light we deceive and degrade ourselves. The express declaration of One whose word admits of no question is, that the dominion of the whole is given to man for his use:—"Replenish the earth, and subdue it: and have dominion over the fish of the sea, and over the fowl of the air, and over every living thing that moveth upon the face of the earth." This grant is universal—free to all, according as their capacity may enable them to avail themselves of it; and in virtue of this it follows that whenever anything in nature is endowed with great activity and power, this activity and power can be made greatly useful to man, and man stands convicted of "burying his talent in the earth," if he does not avail himself of them to the full extent.

We have shown that the martens are remarkable for their energy and activity, and having done so we shall now proceed to a brief notice of the three genera, which it is our more immediate business to explain.

The three sections of these animals as established by Cuvier are *Putorius*, the polecat; *Mustela*; and *Meleptis*, the offensive-smelling animals of South America, which have no common English name.

PUTORIUS.—The animals of this genus, though by no means the most handsome, are the most sanguinary of the whole. Their carnivorous tooth in the lower jaw has no tubercle in the inner side; their tuberculous teeth in the upper jaw are broader than long, and they have two false molars above and three below. Externally their muzzle is shorter and thicker than that of the martens, properly so called, and this shortness and thickness of the muzzle in a carnivorous animal, always indicates an accession of carnivorous character. They do not bear so striking a contrast to the martens in this respect as the cats bear to the dog, and there is not so much difference in their characters, but still there is enough for entitling them to be considered as a separate genus. The species are numerous, and distributed over many parts of the world; and the individuals in most of the species are abundant.

Common Polecat (*P. communis*).—The polecat is one of the most common of the genus, and also one of the most powerful and the most mischievous, while its fur is of very little value, and its flesh so rank as to be rejected even by hungry dogs. Generally speaking, it is about a foot and a half long, and the tail is about half a foot more. Its general colour is brown, passing into yellowish on the flanks, and with some white spots on the head. It is a very active and nimble animal, and remarkable for its boldness. Its body is long but its legs are short, and therefore while it is running its belly appears to touch the ground. It can leap to a great height and distance for its size; and when it leaps for the purpose of seizing its prey, it hits a mortal part with the certainty and the force of a javelin well directed, so that when a rabbit, or even a hare is killed by a polecat, only one feeble shriek is uttered by the victim. It climbs walls with great facility, and no animal is better adapted for getting over rough ground, through brakes, or through crevices in walls and holes in fences, which one would scarcely deem large enough for admitting a rat. It can also upon emergency climb trees; and, indeed, there is no animal which can so readily find access to all sorts of places. In case of necessity it can subsist upon rats and mice; but in general it prefers game of a higher description, and is not very particular as to the kind. It is very destructive of hares, and still more so of rabbits, which, as they are social and hares are solitary, are its favourite prey. Those who have rabbit-warrens endeavour to destroy polecats by every scheme they can invent, indeed it is understood that a single polecat would in time desolate a warren, because if it finds plenty of prey it merely sucks the blood, and eats the brain of one victim and then passes on to another; and in this way it will destroy a great number in the course of one day. It is very apt to infest the neighbourhood of houses, where it prowls nightly for such prey as it can find access to. In the poultry-yard, or in the pigeon-house, it is equally destructive as it is in the rabbit-warren; and, if it can find no other prey, and these are accessible, it will contrive to plunder bee-hives of their honey. In places where there are many rabbits and poultry, and also slovenly hedges and brakes to afford it cover, it is a perfect pest to the farmers. It is very daring, and will not hesitate to take up its abode in barns, hay-lofts, and other places, the possession of which it defends as resolutely as if they were its own property. In the summer season it often frequents brakes and copses

though not the central parts of extensive forests. In such situations it digs a burrow, not very deep but extending five or six feet under ground, and usually terminating under a bush, or close by the tangled root of a tree. It is no easy matter to dislodge it unless by smoke; for its burrow is too small for admitting a terrier dog, and its odour, especially when excited, is offensive even to a proverb—more so, indeed, than that of any other animal in Britain. Anger, or perhaps rather fury, is the only passion which it displays upon such occasions, for it does not appear that fear enters into its composition. When attacked by a dog the polecat turns, and defends itself with great spirit. If the dog is not staunch, so as to go in upon it at once, but stands barking as curs do when they hesitate, the polecat springs at him, fastens so exactly and so severely on his nose, that he is apt to run yelping away from his comparatively small enemy.

The common polecat is found in all the West of Europe, and also in the North of Africa, and it is perhaps most abundant in the middle latitudes of its range. It does not belong to those animals which frequent in such numbers the countries of the extreme north; and the thinness and poorness of its fur point it out as a native of more southerly and congenial climates. Even with us it is not found in the wild uplands any more than in the extensive forests. It is naturally a low-country animal, and peopling and cultivating have no tendency to diminish its numbers. On the other hand, they are rather the means of increase; for rabbits and partridges, both of which are favourite prey for the polecat, increase rather than diminish as the fields are more cultivated. It breeds in the spring, and the litter usually consists of three or four. The mother does not continue to suckle them for any great length of time, but supplies them with eggs and the blood of animals. When she carries the latter to her nest, it is said that she contrives to compress the wound by which she kills them, so as to keep in the blood, in order that it may be sucked by her young ones, whereas, when polecats kill for their own eating, they suck the blood instantly. None of the tribe are good milk nurses to their offspring, their apparatus for this purpose being by no means perfect. Unless when required for the young ones, the mammae are nearly obliterated, and even then they are but little produced. The mammae are ventral, and vary in number; some species have only four, and others as many as eight.

This paucity of nursing in animals which are exceedingly bloodthirsty, as compared with those which have less of that character, or none of it, is a point worthy of attention in animal physiology; and though it has not been systematically noticed, it will be found to be by no means one of the worst keys to the disposition of the animal. The mammae of the female cat, for instance, though no animal shows more attachment to its young, are but little developed in comparison to those of the female dog; these again are less developed than in the female hog, and so are they less developed than the mammae of the ruminants, especially the cow, which may be considered as the most domestic, and the most immediately connected with man of all animals. It would be easy to fill up the chain through the whole range of the mammalia, and it would invariably be found that the bloodthirsty disposition is inversely as the development of the mammary apparatus. The

instances which we have given, which are leading ones, serve, however, to establish the fact. Nor are we without experimental evidence as to the other portion; for (as we have formerly had occasion to remark in the article *LUTRA*) if the young of a carnivorous animal continue to be fed for a long time on milk, or milk and farinaceous matter united, their dispositions are softened, so that they become tame and gentle. If, on the other hand, animal food, and especially raw flesh, is given to them early in life, they become ferocious, and never can be tamed into perfect obedience, or any docility, except such as is flogged into them with the whip. The breeders of dogs are perfectly aware of this circumstance; so that, out of the very same litter, and of two pups, the one of which can hardly be discovered from the other, they can so deal with the one in its feeding as to make it ferocious, and so with the other as to make it perfectly gentle. Even in the human subject there are proofs of this; for people who live upon vegetables and milk are, with equal usage, much more gentle in their dispositions than those who live upon animal food; and when pugilistic combats were, to the shame of human nature, encouraged by many of the misnamed great of England, as manly sports, that passive sort of brutal courage, known by the slang name of "bottom," was cherished in the ruffians by feeding them upon beef almost in a raw state. It is most encouraging to the philosophic student of nature to find, that that which has been proved to him by his own observation, without any reference to natural history, corresponds exactly with that which runs through the system of nature.

The Polish Polecat, (P. Sarmatica.) This species has sometimes been confounded with the common; and, from the peculiarity of its colours, it has sometimes been considered as a cross between the common polecat and the *ferret*. Such, however, is not the case; for the animal is abundant in a state of nature, and that in places where neither of the others is to be met with. It is rather more tropical in its locality than the polecat, being found chiefly in the South of Russia, in Asia Minor, and generally in the countries around the Black Sea and the Caspian. The upper part of the body is bright brownish yellow, beautifully mottled over with small brown and white spots. The under part, the legs, and the point of the tail, are rich brown. The head also is brown; but it is marked with a white line, which proceeds from under the one ear over the eye across the front, and onward to the other eye, and under the other ear, something in the shape of a horse-shoe. The ears, the point of the muzzle, and the chin, are white. In its markings it is a very handsome animal; and on account of these, its skin is in considerable estimation with the dealers in *peltry*; but it is a poor fur, short, thin, and by no means durable, though those who are fond of show are apt to be taken in by its colours. By some naturalists this species has been classed with the true martens; but any one who smells it can tell at once that it is a polecat.

The Ferret (P. furo) is, generally speaking, of a yellowish colour, with the eyes of a red or rosy tint, on which account some have supposed that it is an albino variety of that animal. This is, of course, an incorrect statement; for we have no instance of an albino variety being continued by propagation in any race of animals; and besides, it differs from the polecat, not merely in external appearance, but actu-

ally in the skeleton; which, being the least changeable part of an animal, is the best on which to found distinctions. It has a rib more than the polecat, and an additional bone in the sternum. It is also a smaller and more delicate animal, and suffers much more from exposure to cold. The polecat, although its fur is by no means a polar one, can "rough it" very well, even in the severest storms which visit our lowlands in winter; whereas the ferret has to be kept in the house, and in a box lined with wool, long before the thermometer sinks to the freezing point. Nor are we without the evidence of history as to the southern origin of the ferret. Strabo informs us that in early times a great portion of Spain was literally eaten up on the surface, and drilled into holes like a honeycomb, by rabbits, just as many parts of the Pampas in South America are at present by the viscachio. Countries, when thus taken possession of by those burrowing rodents in such multitudes, are quite unprofitable to man; and scarcely any human means, indeed none which would be repaid by the advantage gained, can rid them of these pests. To bring Spain within the class of useful countries, the ferret was imported from Africa; and it has ever since been more or less preserved in Europe, not domesticated, (for, to soften its disposition would be to destroy its usefulness,) but a subject of the care of those who employ it. To those who feed it, and are otherwise kind to it, it is not gratuitously savage, at least in any very high degree; but very little tampering with it angers it, and makes it bite. When angry, its odour, which is far from pleasant at any time, becomes even less so, and establishes its connexion with the polecat genus. It is considerably smaller than the polecat, being four inches shorter in the body and an inch shorter in the tail; and it is exceedingly slender. It is very bold, however, and its disposition to kill rabbits is most inveterate. It is chiefly used for rabbit hunting, not for killing them; for if it were allowed to do that, it would soon despatch a whole warren, and leave the owner to dig out the dead bodies at his leisure. It is used to "mearth" them, or drive them out of their holes, and it is carefully muzzled to prevent it from biting. The rabbits are not, of course, aware of the perfect harmlessness of the muzzled ferret, and so they scamper out, and are caught, generally by terriers, which watch at the mouths of the holes, and at another time in a net, if the object is to keep the rabbits alive. It is also the very prince of rat-catchers; and as it is not muzzled for this sort of occupation, it slaughters away in a dashing style, and might be very useful in places infested with rats, were it not for the attention and trouble which it requires. In corn stores and mills it might be advantageously kept; and if a snug berth could always be provided for it, it would be very valuable at sea. The ferret, as is the case with most animals when transported to a climate colder than their natural one, spends a great deal of its time in sleep; but the moment that it awakens, it is in a state for action; and slender as it seems, it is capable of undergoing a great deal of fatigue. The period of gestation is six weeks; and two litters, varying from about five to nine, are produced in the year; so that it is a very prolific animal. The female is apt sometimes to devour her own offspring when they are newly dropped; but when she does this, she is very soon ready to prepare for another litter. Altogether the ferret is a most

interesting little animal; and it is not the less so for having been in Europe for at least two thousand years, without becoming so far accommodated to the climate as to pass into the wild state. This is another curious point in the physiology of animals, and one which well deserves attention. Man can inhabit from the equator to very high latitudes; the dog can accompany him in all, and most of the other domestic animals, in the greater part, accommodating themselves to the difference of climate in the course of time; but the more carnivorous animals are, as it were, tied to their localities, and no time will inure them to a climate very different from that of which they are natives.

The *Siberian Polecat*, (*P. Sibirica*.) This species is about the size of the ferret. Its general colour is bright golden yellow, but often with white on the point of the muzzle and below the lower jaw, and brown on the nose and the eyes. It is subject to varieties, however; and it is understood that a few individuals of these varieties are found as far to the westward as France. In its native country, where it is abundant, it resides chiefly in the forests during the summer; but, when the cold weather sets in, it approaches houses, and is very apt to play the same part in farm-yards and pigeon-houses as the polecat and the weasel. It is probable that this species might be rendered very useful in the destruction of rats, as it is more hardy than the ferret. Its fur is much longer than that of any of those which we have yet described, clearly indicating a more northerly origin.

The *Weasel* (*P. vulgaris*) is the most diminutive of its tribe. Its height from the ground, when the back is not arched, does not exceed two inches and a half; and the length of its body is less than eight inches. The tail is shorter than in most of the genus, being about two inches and a half, and terminating in a point. The colour varies a little in the individuals, and still more with climate; but, generally speaking, the upper parts and the legs are pale brown, the throat and belly white; and there are two spots of brown behind each corner of the mouth. The eyes are small and round, and of a clear black colour; and the ears are rather large, and have a fold near the margin, which makes them appear as though they were double. The weasel is very generally distributed over the cold and temperate parts of the world, and it is a very bold and energetic little animal. The flexibility of the weasel, and the agility with which it moves about, give it a wonderful command of all sorts of places. There is a proverb which says, "He builds closely with dry stones who can build out the weasel;" and the saying is true, for the animal has been known to worm its body through a hole less than three quarters of an inch in diameter. It is also a most expert climber, and can ascend a wall or a tree with all the dexterity and expedition of a cat; and as its feet are shorter, and its body longer in proportion than that animal, it can twine round and round so as to elude capture. On the ground it is not a very swift animal; less so, indeed, than most of its congeners; and thus, in an open place, it is soon run down. If, however, there are trees, or walls, or brakes near it, it is in vain to hunt the weasel by the help of any known animal; and, small as it is, no dogs, except the most determined terriers, are fond of having anything to do with it. It springs at their nose or cheek, and there it hangs, inflicting a bite

equally painful and powerful, (for its canines are rough,) and it is so light, that the animal on which it fastens is unable to shake it off. The Scotch name "Whitret," which is given to this animal, is, in the old language of the country, (not the Gaelic,) remarkably expressive of its action and manners; for it implies that it is seen one moment and lost the next. As is the case with the whole tribe, and with predatory animals generally, the weasel remains in a state of repose during the day. This is not always the case, however, for the writer of this article has seen a weasel fairly run down a leveret along a furrow of ploughed land, and seize it by the side of the neck, and instantly finish it, at noon day, and under a bright sun. The weasel is indeed remarkably scientific in the killing of its prey, and fixes on the place where its bite is most speedily mortal, and the blood of the animal most easily obtained, as correctly as if it had studied anatomy sufficiently to entitle it to a diploma; it is doubtful indeed, whether, many of those who have got possession of such a document, could kill a hare or a rabbit, and extract its blood, with the same neatness and expedition as a weasel. The weasel is particularly fond of warm blood; but it is somewhat of an epicure in the matter of flesh. It likes that "high;" and when one smells the store which it generally has in its larder, in favourable situations, one is forcibly put in mind of the distich of the satirist—

"O blast it, south winds, till a scent prevail,
Rank as the ripeness of a rabbit's tail."

This taste is not, however, peculiar to the weasel, or to the group of carnivora to which it belongs; for all carnivorous animals give the preference to flesh with the odour of putridity about it, rather than flesh which is fresh and recent. Here again there arises a curious little point, not unimportant to the human race. The man of wholesome and simple appetite, who lives in great part upon vegetable matter and the product of the living beast without the destruction of its life, and who eats flesh but rarely and as a dainty, likes to have it as fresh and recent as ever he can get it; but, with a thoroughly carnivorous man, the case is different; he must hang up his mutton a fortnight and his venison six weeks, and can in no case relish grouse unless he can eat it with maggot sauce of its own growth. We must not be astonished at this coincidence between man and the other animals in the matter of food. It is the merely animal man that feeds, not the intellectual man; and in proportion as man approximates any animal in the nature of his food, he must approximate that animal in his *gusto*.

We have remarked that the weasel, when on the hunt, or when by any means excited, is an exceedingly energetic and powerful animal for its size; and it is worthy of remark, that its muscles, or working structures, enjoy as complete a relaxation in the time of its repose. During the greater part of the day, unless under peculiar circumstances, such as those to which allusion has been made, the weasel gives itself up to rest and sleep; and it is impossible to imagine a creature giving more perfect and more equal rest to all the working structures of its frame, than the weasel does upon such occasions. It has the utmost degree of relaxation, not only in the muscles of the limbs, but in the muscles connected with the spine, which are, indeed, as much called into action as the others, if not more so, during the leaps which the animal has

to take. If one takes proper judgment of where the centre of gravity is situated, and so puts his stick under a sleeping weasel, and raises it gently from the ground, it comes head and heels together as easily; and with apparently as little pain to itself, as if one were lifting in the same manner a bit of ribbon or an old stocking. So also, if found sleeping, it may be taken up by the head, the heels, or the tail, and swung pendulumwise for at least a dozen times before it begins to awake. In fact, though it is a snappish little animal when awake, there is none in the whole catalogue of the mammalia with which one may take greater liberties when asleep.

Weasels have, we believe, only one litter in the year, which circumstance sets them down as being properly natives of temperate countries, and not of tropical ones; for the ferret, which, though not originally from a region absolutely tropical in respect of latitude, though from one which is certainly tropical in point of climate, has two broods in the year. The female is not, even as brood for brood, so productive as the female ferret, for her litter rarely, if ever, exceeds four or five. She prepares for them a comfortable bed of dry stalks and leaves and soft moss; and we are not aware of any recorded instance of her devouring her offspring, as the ferret sometimes does. The period of her gestation is nearly the same as in that species, and the young ones are blind when they are dropped, as is the case with almost all carnivorous animals. She is an attentive mother, however; and though she has the same deficiency in suckling as the rest of the tribe, she brings them fresh eggs and warm animals quite full of blood in a fluid state. Those stimulating viands whet their young instincts, and cause them to grow apace, so that in a short time they are able to join in the nocturnal forage, and kill their own prey.

The weasel is not so destructive about farm-yards as the polecat; it is a much prettier animal; and though the odour of it is no desirable perfume, it does not offend the nostril to such an extent as that of the other does. For these reasons, the weasel is by no means so much persecuted as the polecat; and in country places it is generally rather a favourite than otherwise. Nor is it undeserving of this favour; for it is a most excellent mouser, and perhaps destroys more of the murine tribe than any other of our wild animals, excepting perhaps the owl. The fur of the weasel is much more close and delicate than that of the polecat, and on these accounts it is held in higher estimation. It also improves in quality in proportion as the animal inhabits a more northerly climate; and the weasel skins of Siberia fetch a price in the Chinese market (the grand mart for furs) equal to some two or three times their weight in silver. Altogether, indeed, the weasel is a very interesting little animal, and may be considered, in our view of the matter, one of nature's *chefs d'œuvre*, because it contains a maximum of power in a minimum of matter.

The *Ermine* (*P. erminia*). The ermine is, in respect of its fur, the most celebrated not only of the polecat genus, but perhaps of the whole marten tribe—the term ermine being applied as symbolical of the robe of a judge, or anything else which is understood to be of unstained or incorruptible purity. It is only in winter, however, that the fur of the ermine is of that snowy whiteness which makes it so much admired, for in summer it is yellowish. It is

rather larger than the weasel, being about nine inches and a half long in the head and body, and three and a half in the tail. Its form is much the same as that of the weasel, and its manners and modes of action are similar, but in a state of nature it does not frequent the same kind of localities. In summer it is, generally speaking, of a yellowish brown on the upper part, and a clear sulphur yellow on the under, with the chin white, and the tail brown, except the extremity, which is black. This is really its gay or nuptial clothing, though it is not the one held in most estimation by those who seek animals for their skins, and not for their manners. There is another reason for this: the skins of animals are not so firm in the summer, neither is the fine under covering of the fur animals so abundant and close at that season as it is in the winter. A summer fur is in fact a thing of small value compared with a winter one in respect both of durability and of warmth; and therefore the superior quality of the ermine's fur goes along with that peculiarity of its colour which is so much admired. The winter colour is, as we have said, the most snowy white; and we are not aware that the fur or hair of any other animal can in this respect come up to it. There is one part, however, which does not change, namely, the tip of the tail, for that remains throughout the year of the most intense black; and when the fur of the ermine is used for ornamental purposes, this black is spotted in little tags over the white, and both colours profit by the contrast.

In all animals, whether mammalia or birds, which put on white for their winter clothing, there is always some part which remains unchangeable, as a sort of hostage that the animal shall return to its summer colour when the season comes round. In the variable hare which occurs in some of the lofty mountain tops in the northern part of Britain, the general colour in winter changes from pale dappled fawn to pure white, but the tips of the ears remain black all the year round. The ptarmigan, which inhabits similar situations, undergoes a change from mottled grey to pure white; but the shafts of the principal quills, and in many cases the webs, retain the black colour which they have in the summer.

The ermine haunts copses, hedges, and meadows, and it is particularly fond of the banks of streams when they are margined with bushes. It is as predatory in its habits as the weasel, or even the polecat, but it very rarely invades the poultry-yard, or even resorts to the habitation of man. The ermine, as well as the weasel, has been tamed, and made to show some attachment to those who were kind to it; and this we might be prepared to expect, because all the marten family, from the nature of their food, and the means by which they have to obtain it, must be animals of considerable intelligence and resource. From what has been already remarked, however, the taming of them must be begun at a very early age, and before they have tasted blood, otherwise it can never be perfectly accomplished. The inducements to tame such animals are not, however, very great, because the only uses to which they can be applied are sneaking rabbits and killing rats and mice.

The *Mink* (*P. Lutreola*). This is an animal of the North-east of Europe, and probably of the countries beyond, and in some of its characters and its habits it makes a slight approach to the otters. Its feet are partially webbed, and it frequents the margins of the waters, feeding chiefly upon frogs and crabs. In its

structure it approaches more nearly to the polecats than to any other genus of the martens; but it differs from them in habit, as above mentioned, and also in its odour, which is that of musk, and not so strong as to be rank and offensive. The fur of the mink is not so much prized for its colour as that of the ermine, but it is of better quality, being more close and warm, and also more firm and durable. The colour is maroon, approaching to black, with the last part of the tail black and the chin white. There is very little reflection of light from the fur, but it is exceedingly soft and beautiful, and fetches a high price in the market. The mink, from its aquatic habits, does not come near the habitations of men, and thus does not incur their displeasure for any depredation which it commits on their property. This, however, does not ensure it a safe dwelling by the banks of those lonely rivers which are its favourite haunts; for, though its conduct does not awaken the revenge of mankind, its covering stimulates their cupidity. From the nature of its haunts, and from its being hunted in the winter, less is known of the domestic manners of the mink than of most others of the genus; but it resembles the rest so much in its organisation, that in all probability its whole character, with the exception of haunt and food, is nearly the same.

The *Vison* (*P. Vison*) is an American species, very much resembling the mink both in its appearance and its habits. Like that animal, it has the feet partially webbed, but it wants the white on the chin, though it has sometimes the white line on the throat. Its size is nearly the same as that of the mink of North-eastern Europe, and its fur is of equal, if not superior quality. It is found both in the United States and in Canada, only much more abundantly in the latter country. Like the European mink, it inhabits the margins of the waters, and feeds upon reptiles and fishes. Indeed, both species are to be considered as a sort of intermediate link between the polecats properly so called, and the otters, being more aquatic than the one, and less so than the other.

The species which we have enumerated are the principal ones of the polecat genus which inhabit the temperate and cold regions of the world. A few others are indeed mentioned by different authors, but it does not appear that there are any grounds upon which these can be well established as species. Most of them resemble either the ermine or the mink, and both of these are subject to variations of colour, the only circumstance upon which the supposed species are founded. In the ermine, especially in its winter dress, and that is the dress in which it is most valuable, and in consequence most sought after, we might be prepared to expect those variations in colour. All animals which change from any other colour to white during the winter, do so as an adaptation to the cold, and consequently the extent of the change must be in proportion to the degree of cold to which they are subjected. Those with which we are most familiar are the alpine hare and the ptarmigan, already alluded to; and it is matter of observation that they do not change so completely to white in mild places, or in mild winters, as they do when the place or the season is more severe. It is quite natural to suppose that the ermine, which is a seasonal animal in its colours as well as they are, should be affected in a similar manner by difference of climate or difference of season, and that ermines

which are caught in warm places or mild winters should retain a portion of their summer colour. The change, too, is gradual, not instantaneous, and the white comes on in patches, so that an ermine caught early in the season is almost sure to be mottled; and, were it possible or desirable to catch an ermine every three or four days, from the beginning to the end of the change in the colour of its fur, there is little doubt that a lover of varieties would be gratified by as many varieties of ermines as there were catchings, though the greater number of them might be of the very same litter. It is thus of the utmost importance to attend to the colours which polar animals undergo in the course of the very variable seasons to which they are subjected, before coming to any conclusion as to what is a species or a variety, and what is not. As the mink inhabits lower down than the ermine, and, generally speaking, not quite so far to the north, it is not subject to seasonal variations of colour. It does appear, however, to be subject to very considerable variations in the white upon the chin, the throat, or both: sometimes it is on the one, sometimes on the other, sometimes on both, and sometimes wanting altogether; so that, in fact, it ought to be discharged from among the descriptive characters of the animal.

The warm regions of the world have their polecats as well as the colder ones, though they are not nearly so numerous in the former, and their skins there are of little or no value as articles of commerce. On this account they have been much less studied, and the studying of them has been comparatively recent, so that there may probably exist in the richer parts of the tropical countries many more species than we are yet acquainted with. The oriental isles are the places where they are most likely to abound, as these are the most fertile spots on the face of the globe; accordingly, there have been two species noticed in the island of Java.

Javanese Polecat (P. Javanica). This species is between six and seven inches long, and remarkably thin in the body. Its general colour is nearly the same as the summer dress of the ermine; but the cheeks are white, and there is a white spot on the front of each eye. The point of the tail is furnished with a brush of long hair, and the feet are abundantly covered with fur, which last circumstance forms a very marked distinction between it and the next species.

Naked-footed Polecat of Java (P. nudipes). This species is frequently called the Java ferret. It is rather less than the polecat of Europe, but larger than the ferret. The general colour of its fur is a very brilliant golden red, and the head and tip of the tail are white. Its most distinguishing character is the perfect nakedness of the soles of the feet. It has been rarely seen by Europeans, and nothing is known of the manners or the habits either of it or the preceding species, further than what may be inferred from their similarity to the rest of the genus.

African Polecat (P. Africana). This species is about ten or eleven inches from the point of the muzzle to the root of the tail, and the tail is about six inches more. Its general colour is russet brown on the upper side, and yellowish white on the under, with a band of russet along the middle of the under part. It is understood that the known specimens come from the western part of central Africa; but the precise locality is not known, neither are the habits. It bears, however, so close a resemblance to the rest of the

genus, as to leave little doubt respecting its character.

Madagascar Polecat (P. striata). This species is about the same size as the European polecat; but it is very differently coloured and marked. The upper part is of a rich deep brown, with five longitudinal lines of white, one along the ridge of the back, and two on each side. These converge toward the tail, which is entirely white; and the under part of the body is also white, but with a shade of grey.

The Cape Polecat (P. Zorilla). This species is not very accurately named; for though it is found in Southern Africa, it is not confined to that part of the continent. It has been met with near the Senegal and the Gambia; and there is little doubt but that it is generally distributed over all the country to the south of the Great Desert wherever the soil answers to its habits. There have been some mistakes about this animal; for it has been described as an American, and as belonging to the mephitic animals of the southern part of that region of the world. These opinions are erroneous, however; for the zorilla is an African and a true polecat, and there is no true polecat in South America, at least so far as is hitherto known; though it is probable that some may exist in the rich wooded districts of the tropical parts. The name, at all events, is South American, and was, we believe, originally applied to one of the mephitic animals of that country; and we rather think that Buffon is chargeable with the misapplication of it to this animal. *Zorilla* means little fox, and was given to the fetid animals of South America, on account of the intolerable odour which they emit. It is rather a large animal, as compared with some of the race, though inferior in size to the polecat of Europe. The length of the head and body is rather more than a foot, and that of the tail about eight inches. Its general colour is black, spotted with white on the head, and streaked with longitudinal white lines on the back. Those spots and lines have always very nearly the same position, but they differ greatly in size, so much so, that at a little distance some specimens appear entirely black, and others almost white. This differs from the rest of the genus, in having the claws better adapted for burrowing in the ground than for climbing, which would seem to indicate a difference of habit from the rest; but what that difference is, is unknown, and in every other respect this animal resembles the rest of the genus.

The enumeration which we have now given comprehends all the species of polecats which are well established; but it is highly probable that, in foreign countries, there are many more, inasmuch as these are nocturnal animals in their habits, and so conduct themselves that they are not easily observed. We must bear in mind too, that, of the wild forests in the tropical countries, not one mile in a thousand has yet been explored by Europeans.—We now proceed to the next genus.

MUSTELA. The animals of this genus, though they have much general resemblance to the polecats, yet differ from them in so many particulars as to warrant the generic separation of the two. The martens have not the offensive odour of the polecats, but on the contrary the smell of some of them makes a slight approach towards fragrance. They are also much more pleasant to look at. They are more elegant in their shape; and there is something in the expression of a marten which tells at once that, though it is as brave as

a polecat, or even more brave, it is not so cruel. And when we come to examine the teeth, we find that they justify the impression which is made by the appearance of the animal; and perhaps if a little more attention were paid to the connexion between the expression of animals, and the structure of those organs which determine the nature of their food and their mode of procuring it, natural history would profit not a little by the result. The martens have one false molar more than the polecats, in each side of the jaw, both above and below, and they have a little tubercle or heel on the inside of the carnivorous tooth, which diminishes its carnivorous character, and makes it in a slight degree a bruising tooth, not a tearing one. It may seem that these are slight differences; but it is by attention to such slight differences that we are enabled to become thoroughly acquainted with the nature and characters of animals.

In addition to those distinctions which we have mentioned between the true martens and the polecats, there are some other polecats. The martens keep to the woods and wilds, spend their lives peaceably there, and never invade the pigeon-house or poultry-yard; and as Nature has destined them for a somewhat severer life than the polecats, she has clothed them in a superior manner, and also given them superior powers of locomotion. It is delightful to contemplate how beautifully Nature does these things. If the average temperature which one animal has to bear is but a few degrees colder than that which another has, a difference is made in the clothing of the former, so as to put them on a perfect equality in point of endurance. Also, if one animal has on the average to travel a mile more a day for its food, muscular power in proportion to its weight is given it to the exact point of compensation. Now, who, we ask, but a Being infinitely wise, knowing all knowledge, and seeing everything to the end even before the beginning, could have planned and executed those wonderful adaptations, or rather, according to our view of the matter, could have endowed them with powers?

The *Common Marten* (*M. martes*) is about eighteen inches long in the body; and the tail, which is much covered with hair, especially about the point, is about ten inches long. It is thus longer than the polecat, and far more handsome in its form. Its nose is softened down, its head slender, its ears broad, rounded, and open, its eyes lively and sparkling but not ferocious, and its whole aspect, to use a homely expression, "just an animal that one would like." Its odour, too, instead of being disagreeable, is a positive perfume; and its fur is as rich as its form is handsome. On the back, the sides, and the tail, the woolly fur is very thick and soft, and the long fur smooth and shining. The hairs are annulated, the roots being ash colour, the middle length chestnut, and the points black. These give a varying and not easily described colour to the whole. The head is reddish brown; the legs and upper part of the feet chocolate brown, and the plant of the foot is thickly covered with woolly fur, like that on the body, so that the marten treads softly. The feet are well developed; the toes have considerable freedom of action; and the claws are strong, sharp, and crooked, well adapted for climbing, but not retractile, and therefore not used for clutching prey. There is some difference of colour in the under part, but it certainly does not amount to a specific difference, or perhaps even constitute a permanent variety.

The under part in all is of the same general colour as the upper part, only paler; but the breast in some is pure white, and in others whitish yellow; and this constitutes the distinction to which we have alluded. In other respects there is not a shade of difference between the one and the other; and it is worthy of remark, that the yellow on the breast occurs more frequently in the warmer latitudes inhabited by the martens, and the white more frequently in the colder latitudes.

Common Marten.

The general residence of the common marten is in woods and copses; and the nest is formed in a hollow tree, a chink of a rock, or a hole in a wall, if the place is sufficiently sequestered. It is well formed of dry grass and moss; and it is understood that the female breeds in spring, and again in autumn, the litter varying from three to seven. "If taken sufficiently young, and before it has tasted blood, the marten can be tamed with the greatest ease, and it is an exceedingly good-humoured and playful creature. There seems, however, to be an instinctive love of freedom and the wild wood inherent in the very nature of the creature; for, though it is ever so playful, and ever so good-natured, it lets slip no opportunity of regaining its liberty and joining its wild companions. The marten has thus another noble trait in its character—it can be tamed, but it will not be enlaved."

There is another strong instinct which the marten evinces, even when tamed—it has an implacable hostility to cats, and lets slip no opportunity of springing upon them and inflicting a mortal wound. In the forests, diminutive as it is in comparison, it battles stoutly with the wild cat; and we shall venture to quote from "The British Naturalist" an account of one of these battles, as from an eye-witness. "In the year 1805, a gentleman, on whose veracity we can depend, witnessed one of those combats in the Morven district of Argyleshire. In crossing the mountains from Loch Sunart southward, he passed along the bank of a very deep-wooded dell, the hollow of which, though it occasionally showed green patches through trees and coppice, was one hundred and fifty or two hundred feet from the top. The dell is of difficult access, and contains nothing that would compensate the labour, and thus it is abandoned to wild animals, and, among others, to the marten, which, though the skin fetches a high price, is not so much hunted there as in more open places; because, though they might succeed in shooting it from the heights above, they could not be sure of removing the body. Thus it is left to contend with the mountain cat for the sovereignty of this particular dell, and both are safe, except when they approach the farm-

house at the bottom of the hill. The contest then lasted for more than half an hour, and both combatants were too intent on each other's destruction to shun or fear observation. At last, however, the marten succeeded in falling upon the right side of the cat's neck, and jerking his long body over her, so as to be out of the reach of her claws ; when, after a good deal of squeaking and struggling, by which the enemy could not be shaken off, the martial achievements of puss were ended in the field of glory."

The conduct of this warfare is not unworthy of attention, and therefore we should quote a few lines descriptive of it from the same work.—"The onset is one of some skill on both sides. The aim of the cat is to pounce with her paws upon the head of the marten in such a way as that the claws may destroy or wound its eyes, while her teeth are imbedded in its neck ; and if she can accomplish that, the fate of the marten is decided. That, however, if done at all, must be done in a moment, and if it be lost, there is no repairing the mistake. The spring of the wild cat is larger than that of her opponent, and the cat takes up her position so that she shall, if possible, alight upon his head with her full spring and impetus. To distract her attention, he keeps moving his head from side to side, and if he succeeds in this object, he rushes to close quarters by a side-movement. If the spring of the cat takes proper effect, there is a struggle, but not of long duration ; and it is the same with the opposite result, if the cat miss and the marten fasten, during the short pause of exhaustion after the spring. Here we may notice another curious feature in the economy of the feline race. It has been remarked of even the most powerful of them, that if they miss their object when they spring, they sneak cowardly away, and do not return to the attack for some time, if indeed they return at all. Now the fact is, that it is not cowardice, but exhaustion. The gnashing with the teeth and the talons seems to be the reaction by which the motion of the spring is balanced, and the tone of the animal kept up ; and if it fail in that, it takes a while to recover the use of its springing muscles. Probably the violence both of the spring and the exhaustion are connected in some way or other with the electric state of the body, but that is a point not easily to be settled. Should both miss, the contest is renewed, and seldom, in the observed cases (which are not indeed very numerous), given up until the one be killed ; and in the protracted contest the marten is always the victor, as the cat is first exhausted by the greater weight of her body and the violence of her leaps."

Interesting as the martens are, and common as they are in most parts of Europe, their natural history is by no means clear and satisfactory. As to their manners, indeed, and their anatomical structure, which is of course the foundation of those manners, there can be neither mistake nor difficulty ; for they are so perfectly alike in these respects, that it is of no consequence upon which of them, if indeed there are really more than one, the description is founded. The usual distinctions are, the common or pine marten, which is found only in close forests, and nestles in the holes of trees ; and the beech marten, which is found in more cultivated places, and nearer the habitations of man, which it sometimes plunders in a similar manner to the polecats.

It should seem, however, that these names are not only local, but that they are interchanged with each

other in the different localities in which they predominate, the one in one locality, and the other in another. Thus, the common marten of the warmer parts of Europe, and, generally speaking, of England, if we except some of the wooded mountains toward the north, is really the beech marten, which is the only marten of these localities. On the other hand, if we go to the forests on the Scotch hills, or to those of the North of Europe, or of Asia, we find that the pine marten is not only the common marten, but almost the only species that is met with. When found in the forest, the marten is of rather larger growth than when found in open and lowland places, which shows that those wild localities agree best with its nature. As is the case with all animals that inhabit more upland, and are of course exposed to a lower temperature, the fur of the marten, when inhabiting the wild woods, is closer and firmer than when it inhabits warm situations. It seems, indeed, that these animals are affected in their size and colour by even moderate differences of climate. The martens of Siberia differ a good deal from those of Europe, and we might be prepared to expect this, from the great difference between the summer and winter in Siberia. But then, the Siberian ones differ from each other as much as either of them differs from the European ; and when we turn our attention to the same species in the North of America, where it is particularly abundant, we find similar differences occurring.

It has sometimes been supposed that the different tint of the pale colour on the throat and breast of the marten constituted a different variety, if not a different species. This, however, is exceedingly doubtful ; for there are in all countries which martens inhabit some with the breast inclining more to white, and others with it inclining more to yellow. This difference, too, is always accompanied with a different shade in the darker part of the fur. If the throat and breast have a pretty deep yellowish tinge, the fur on the upper part is always of a deeper and richer brown colour. This, we believe, happens most frequently among those which do not quit the forests, but live in the shades of trees ; and perhaps we might expect it, from the more uniform temperature of the day and the night in such places. The shade, and the constant evaporation which is going on in a forest during the day, both tend to keep it cool, and the evaporation keeps the air immediately over a forest and between the trees more saturated with moisture, and therefore nearer the dew point than the air is over a plain. By this means the nocturnal evaporation of a forest is less in proportion to the diurnal than that of an open plain, and consequently the night is warmer. Indeed, as the marten remains quiescent for at least great part of the day, except when hunger forces it out, and as even then it preys chiefly or exclusively in the shade of the branches and leaves, the marten enjoys a pretty uniform temperature during the twenty-four hours. We have often had occasion to remark, that there is nothing which tends more to the general health of an animal, and the preventing of wear and tear in its system, than a uniform temperature ; and this, as we have now explained how it is brought about in the forest, seems to be the principal reason why in the marten there is, both in its appearance and its fur, a superior animal to the marten of the open plains ; and this, when duly considered, appears sufficiently to account for all the differences

that are observable between one marten and another, at least in so far as the two observed varieties of Europe, and those which answer to them in other parts of the world, are concerned.

The great esteem in which the furs of this tribe of animals have been so long held, and the severe labour which must be undergone in order to procure their skins, have tended not a little to confuse the natural history of them. The quality and colour of the fur are, of course, the properties upon which its market value depends; and they consequently occupy the foremost place in the thoughts both of the hunter and the dealer. With the exception of the ermine, the skins of all the rest are not only esteemed more beautiful in proportion as they are darker, but they are actually better in quality. For this reason a classification, according to colour, of the skins of the very same animal is not only natural, but almost necessary. On the other hand, the labour that must be undergone, in finding such small animals in the wilds, and the fact of the whole race being solitary animals, of which one only can be captured at a time, renders the real hunting one of the least profitable occupations in which human beings can engage; at the same time that it is one of the most severe, both in bodily labour and exposure to the weather. For these reasons the hunting of the fur animals can be practised only by persons of the very humblest class, who are incapable of doing anything better. Such persons cannot be expected to have any knowledge of the principles of natural history, or any desire to promote the practice of it; and we require no other proof of this, than the fact that, with the exception of one or two spirited agents in the wilds of Canada, whose occupation was much more that of purchasers of furs than original procurers of them, the hunters of fur animals, and the dealers in their skins, have added nothing whatever to natural history. We have a remarkable instance of this in the case of the chin-chilla of the western slopes of the southern Andes. The skins of these animals had been in common use by thousands for many years before any person in Europe knew from what part of the world they came.

In Siberia there is the same distinction made between the marten of the wild woods and the marten of cultivated places, as there is in Europe. That which has the latter habit often levies contributions on poultry and pheasants, and slaughters away, so that it kills a great number in a night. It is said also sometimes to nestle in obscure corners about barns and other outhouses, and in fact to have a good deal of the habits of the weasel. Its fur is much less esteemed than that of the marten of the woods, and therefore it is much less frequently sought after. Some of the American martens differ considerably from those of Europe, at least in their colouring; and this will render a slight notice of one or two of them necessary.

The *Canada Marten*, or *Pekan*, (*M. Canadensis*), is about the size of the martens of Europe, or perhaps a little larger. It has the feet, the tail, the muzzle, and the under part of the body deep reddish brown; the ears whitish, and the rest of the body greyish brown, varied with black. It is understood to be subject to some seasonal variety of colour, and individuals also differ greatly, some being almost black on the upper part. It occurs in considerable numbers in the country after which it is named; but its habits do not differ materially from those of the others.

The *Huron Marten* is another coloured variety, differing considerably from the former. It is all over of a bright pale brown, but with the paws and extremity of the tail often darker than the rest. Hardly any positive description of its colour can be given, however, because it is subject to much variation. This variety, (if indeed it is a variety, and not a mere change of colour, produced by a different climate,) appears to stand to the other Canada one in nearly the same relation as the marten of the forest stands to the marten of the fields in the eastern continent. We are, however, so ignorant of the summer appearance of the American fur animals, from the inaccessibility of their country, except when it is frozen, as to be unable to come to any positive conclusion with regard to what is a species permanent for generations in its character, and what is a variety incidental only to the individual.

It is when these animals are in their winter attire that they are sought after; and though they are active at this time, it is by no means their characteristic season, for the summer covering is to be regarded as that most connected with the physiology of the animal; and unless this is as well known as the other, we can come to no very safe conclusion of such a nature as to satisfy the naturalist, how well soever those winter distinctions may answer for commercial purposes.

The *Sable* (*M. zibellina*). This is by far the most highly esteemed of the whole genus of the true martens, as it ranks higher among them than the ermine does among polecats. In form and size it does not differ greatly from the martens, and there is also a slight resemblance in the character of the fur, though that of the marten is very inferior in all those qualities which are valued in furs. Though the fact is sometimes stated otherwise, the teeth of the sable are of exactly the same character as those of the martens, which indicates the same kind of living, and the capacity of partially subsisting upon vegetable matter when animal food is not to be had. But there is one character of the sable which points it out as belonging to a different locality, and that is, the feet being completely covered with fur down to the claws. Thus the sable is a more northerly animal than any of the martens, and an animal much more of the wilds. Accordingly it is never met with in warm places, but only in the extremest wilds of Siberia, beyond the positive forests, and on the margins of the polar ice.

The skin of the sable is exceedingly valuable; and though the animal is a very small one, a single skin fetches a large price. The animal is accordingly sought after with the greatest assiduity, and it may be said, that the desire of procuring sable skins has conducted more than anything else to the discovery of the extreme north and north-east of Asia. It is during winter that this hunting is carried on, and it is described as being more severe than the hunting of the fur animals in America, because of the vast accumulations of broken ice, covered with snow, which skirt the shores of the sea, and contain between them the most dangerous pitfalls, concealed by snow. In America, the margin of the polar sea is no doubt as wild in itself as it is in Asia; but the American hunting ground does not come up into so high latitudes as the sable ground in Siberia; and thus, though the American hunter has long roads and severe cold, he is not beset by so many dangers.

We need hardly mention that the fur of the sable is a rich brown, marked with some white spots on the chin and sides of the head. The part where these spots are is not as much valued as the rest; and the furriers work it up separately, and give it the name of "sable gill."

Like the ermine among the polecats, which is the most immediate associate in locality with the sable, among that genus of the tribe, the sable is subject to an annual change of colour. In summer it is black, and the change that it undergoes, naturally follows the general law of being more perfect in proportion as the cold is more severe. The cold of the sable's country, however, is sufficient every winter for accomplishing anything that cold can accomplish, whether it reside in the places which we have mentioned close by the polar sea, or on the cold heights of the mountains further south; and therefore the sable skins obtained during the winter are more uniform in colour than those of animals which inhabit less rigorous places.

In many places of Siberia the hunting of the sable is a duty imposed by the Russian government upon the exiles from that country; and to them, when they first enter upon it, it is the most dreadful to which human beings can be subjected. They are unacquainted with the country; and instead of knowing where to discover and how to procure the animals, of which they are compelled to find a specified number, they can hardly make their own way across rocks and chasms, fallen trees, and countless other irregularities, all hidden under the snow; and thus many of them perish in that dreadful wilderness.

The sable, as we might expect, partakes of the characters of a tree animal and a ground animal jointly. It can climb; and it is understood to climb for those wild berries which remain upon the branches in winter, as well as for birds and their eggs and young during the summer. It also hunts prey upon the ground; and though it is of course not capable of running down a hare in fair chase, it is very capable of despatching one if it comes upon it by surprise. It is also sure to follow the more powerful predatory animals, the polar bear, the wolf, and the glutton, in order to obtain a share of their prey. In its disposition it is not a ferocious animal, but can be tamed, and will show some affection in a domestic state. In this state it subsists indiscriminately upon animal and vegetable matter, and is said not to be so prone to make its escape to the wilds as the marten.

We have now enumerated the principal species and the leading varieties of the polecats and the true martens, as they are found in the eastern continent and in North America. Had we attended to the differences of colour as they are noticed in museum specimens, which are often selected for their curiosity and not for their correctness, we should have had a much larger list; and there are some small weasel-looking animals of South America which have not been very accurately described, that appear to belong to a different family, though they have sometimes been included in this one. These, according to the best accounts, are plantigrade animals, and therefore they have neither the swift motions nor the energy of the present family. We have already assigned some reasons why the true polecats and martens should be in a great measure confined to the cold and temperate regions of the world, and that, in such a country as South America especially, the smaller pro-

datory mammalia should be chiefly of an insectivorous disposition; and this last appears to be the predominating character of those South American animals to which we have alluded as being sometimes included in the present genus.

MEPHITIS.—The mephitic animals, at least those of South America, which are the best known, form a single genus, not very numerous in species, nor greatly so in individuals. The name by which they are known is highly correct and descriptive; for it is impossible to imagine anything more offensive than the odour which these animals give out when they are alarmed or irritated. They differ more from the polecats and the martens in the general appearance of their bodies than these animals do from each other. In number their teeth are the same as those of the polecats; but they have the tuberculous tooth in the upper jaw large, and two tubercles on the inside of the carnivorous tooth in the lower jaw, which reduce its sanguinary character below even that of the martens, which have less bloodthirsty habits than the polecats. In their forms these mephitic animals bear some resemblance to the badgers, sufficient to lead us to conclude that there would be some similarity in their habits and also in their food.

The general characters of these animals, besides that of the teeth as given above, are, the body very low, the head long and pointed, the ears small, the legs short, the claws on the fore feet large and strong, and well adapted for burrowing in the ground. They have not that arching and flexibility of the spine which characterises the two genera of which we have spoken; and their bodies are not adapted for making way through such small apertures in proportion to the relative sizes of the animals. They accordingly inhabit the ground, live in burrows, and when undisturbed, they are, like the badgers, very peaceful animals in their habits. Their markings also bear some resemblance to those of the badgers, consisting chiefly of longitudinal lines of white upon a dark ground. One, at least, is met with in the southern parts of the United States, and described by Catesby in his History of Carolina. It does not appear that this one is at all different from the one which occurs in South America to the eastward of the Andes, further than having the white lines more produced in some specimens than in others. This species is

The *Chinche* of Buffon and other authors; but it has also other names, and indeed there has been some confusion among all the rank-smelling animals of South America, from the fact of the Spanish indiscriminately giving them the name of *zorillo*, or little fox. The length of this species is about a foot and a half, exclusive of the tail, which is about half as much more, and very thickly covered with hair. The muzzle is very pointed, the eyes, like those of all digging animals, small, the fore part of the body altogether small, and the air of the animal dull and stupid. The colours are generally black and white; but their distribution and proportion to each other upon the body vary so much that they cannot be depended upon as portions of the descriptive character. It should seem also that these differences of colour are attended with difference of size; but what the particular circumstances of climate are have not been made out. They are, however, the reverse of the martens in their geographical distribution, and therefore we may conclude that climate has the very opposite effect upon them, and that in a place where

the martin family would thrive the best, these animals must be in the worst condition. This species is described as inhabiting the margins of the woods rather than the depths of the tangled forests; and it sands charged with attacking farm-yards and destroying poultry. We should feel inclined to doubt this part of its character, though it is highly probable that it may destroy eggs and also the callow young of birds. When the animal is not alarmed, the odour of it, though offensive certainly, is not intolerable; and it appears that the animal uses its battery for the same purpose that a vessel uses her stern-chase guns, namely, to retard the progress of an enemy, and thus increase the chance of escape. The offensive odour is confined exclusively to the apparatus by means of which it is produced and emitted; and when this apparatus is removed, it is said that the Indians, and even the Guachos, do not hesitate to eat the flesh of this animal, nor eat it without a high relish, though not equal to the flesh of an armadillo roasted in its own shell. When the animal is pursued and annoyed, the battery is discharged, not in mere gas, but in a liquid, which, however, instantly evaporates, and is so buoyant and dispersive, and at the same time so powerful, that it will taint the air for a mile or even several miles round. Nearer at hand it is perfectly intolerable, and the staunchest dog is instantly arrested by it. We do not give implicit credit to all the stories which are told of it, although we believe it would be very difficult to exaggerate its offensive qualities. As a specimen of what is said, we quote the following short passage from Kalmaen. "In the year 1749," says he, "one of these animals came near the farm where I lived. It was in winter time, during the night, and the dogs that were on the watch pursued it for some time, until it discharged against them. Although I was in my bed a good way off, I thought I should be suffocated; and the cows and oxen, by their lowings, showed how much they were affected by the stench. About the end of the same year another of these animals crept into our cellar, but did not exhale the smallest scent, because it was not disturbed. A foolish woman, however, who perceived it at night by the shining of its eyes, killed it, and at that moment its stench began to spread. The whole cellar was filled with it to such a degree, that the woman kept her bed for several days after, and all the bread, meat, and other provisions that were kept there, were so affected, that they were obliged to be thrown out of doors."

D'Azzara gives a similar account of the extreme offensiveness of the discharge given out by the mephitic animal of Chili, which is an animal resembling the ferret in many respects, though differing from it in others. We have not thought it necessary to give any one of the many names which this Chilian animal receives; because there is not any one of them expressive of its character; and in its manners it is not very different from the chinche. Like the other, it is very subject to variation of colour, and the colours of the male and female are rarely the same, so that a description founded upon colour would describe merely the individual and not the species, and thus be in effect no description at all. According to D'Azzara, the Chilian animal lives in the open country rather than in the forests; and we might expect this, for the general character of at least a great part of Chili is more that of open country than of forest. It hovers in the ground; and though the naturalist to

whom probably we are indebted for our best information respecting it describes it chiefly as feeding upon eggs, insects, and such birds as it may occasionally capture, yet we strongly suspect, that from the vegetable character of the teeth, and its excellent provision for burrowing, it adds both earth-worms and bulbous roots to the food which he mentions. It is represented as having an easy and gliding motion, but not a rapid one; so that, though it can gallop when danger puts it to its speed, its motion is not faster than a man can follow it. It is not known to attack any of the mammalia, and it is altogether very mild and inoffensive in its manners. The Indians seek after it with some eagerness, and relish its flesh. When they pursue it they tease it with a long cane, in order to make it discharge the contents of its offensive apparatus. When they once succeed in this, the animal is taken with the greatest ease and without offending any one; and they have the art of extracting this apparatus, which of course destroys the power of ever after emitting the odour, and the animal may then be kept in the house in a completely domestic state.

The secretion which these animals emit, and which is so volatile in its nature and so offensive in its smell, has not, we believe, been subjected to anything like an accurate chemical analysis, and thus its composition is not known. Indeed, the analysis of this substance would defy the nose of almost any chemist, how well inured soever to the unsavoury smells of a common laboratory. It is generally supposed, however, to have phosphorus in its composition, or, at all events, to have phosphorescent properties, so that, when the animal discharges it in the dark, it comes off like a jet of light, and thus it is literally a species of firing. When it takes effect upon the skin in substance, it appears to be caustic and painful in its operation, as well as offensive to the smell. Old dogs, who have experience in the pursuit of this animal, are not fond of going in upon it behind at any time, and will not venture until it has made its discharge; but young dogs readily run in upon it, and as its march is very slow, they soon near it; when they do so, however, they are certain of receiving the offensive discharge right on the nose, and this throws them into a state of the greatest apparent agony. They turn away from the animal with great fear, scrape the earth with their paws, and bury and rub their noses in it with piteous whinings, and tear them with their claws till they are all lacerated and bleeding. They do not desist from those demonstrations of suffering until they are completely exhausted, and fall panting to the earth through fatigue; and if one of them has suffered in this manner, nothing can induce him again to follow an animal of the same species.

If this matter is projected upon the clothes of a human being, those clothes are useless ever after, because no means have been discovered by which the offensive smell can be removed, at least in any reasonable portion of time. Hamilton Smith, whom Cuvier very justly characterises as "*très savant naturaliste*," mentions that Mr. Skidder, of New York, had a suit of clothes stained by this matter, which were washed with the greatest care, and afterwards suspended over the top of the house, not less than fifty feet from the foundation, and yet the rank odour was strongly smelt a long way off in the streets. Smith further mentions, that when one day travelling by coach in some part of the

United States, the coach came up upon a chinché (or skunk, as it is called in North America), which was endeavouring to creep through a fence. It was unable to accomplish this before the coach came close upon it, and so it discharged its artillery against the driver. This artillery did not take effect on him, but on a buxom American lass, who, occupying part of the driver's seat, was between him and the animal, and so completely did it pollute her clothes, that they never could be used afterwards. Whether Smith and his fellow-travellers were gallant enough to sympathise with this Transatlantic beauty while under the effects of this "untoward" accident, and remain in the same vehicle with her, is not recorded; but if they did, it was of course done at no common olfactory sacrifice.

It is not a little remarkable, that the whole of this tribe of animals are furnished with offensive odours in proportion either to their sanguinary habits, or to their inability to defend themselves by the ordinary means of cleanly warfare among beasts. The inability of defence appears to be the property with which this offensive odour is most largely associated; and in the true martens, which are the most lively and energetic animals of the whole, though the least disposed to interfere with any other mammalia, the odour, so far from being offensive, is agreeable; and in the viverridæ, which, in their general characters, stand somewhere between the dogs and the hyenas, the odorous secretion has a strong musky smell, and is by many highly prized, and purchased at a considerable price as a perfume.

There is one animal which, in its teeth and in its feet, bears a great resemblance to these mephitic animals, but it is totally different in the snout, the tail, and the general shape and covering of the body, so that it forms, at all events, a separate genus, and ought perhaps to be regarded as belonging to a tribe quite distinct from that of the martens in any of the three genera. We shall therefore describe it as such, and without positively referring it to the family.

THE TELAGON (*Midas meliceps*). This is an animal of the Oriental islands, and was made known to Europeans by the researches instituted by Raffles in Java, which revealed so many of the natural wonders and peculiarities of these most singular and productive countries. The first and best account we have of it is in Dr. Horsfield's Zoological Researches in Java, and therefore our notice may be most conveniently, as well as usefully, given in his words. It will be observed, that he calls it by a name somewhat different from that given to it by Cuvier, which we have adopted, but it is the same animal. "The Teledu," says Dr. Horsfield, "has a peculiar external character and physiognomy. Although it generally agrees in size with the polecats of Europe and America, the circumstances which influence its appearance are entirely different. The heavy form of the body, as well as the head, gradually narrowed to an obtuse point, call to mind the figure of a hog. The shortness and strength of the neck, and the manner of walking, by placing the entire sole of the foot on the ground, contribute further to give the animal a sluggish appearance. The eyes are placed high in the head, and in their size and disposition have considerable resemblance to those of the hog; the eyelids are rigid, and well provided with eyebrows, consisting of minute bristles; the irides are of a dark colour, and the pupil is circular; the ears are nearly concealed

by the hairy covering of the body; but these organs are provided externally with an oblong concha, which surrounds the posterior part, and, passing the lower extremity of the meatus auditorius, forms a small curve inwards. No whiskers are perceptible, but a few straggling hairs arise from the upper lip. The covering of the teledu is adapted to the cold region which it inhabits. The fur is composed of long delicate hairs, silky at the base, which are closely arranged, and afford a warm coat to the body. On the sides of the neck the hairs are lengthened, and have a curved direction upward and backward; on the top of the head, meeting from before and behind, they form a small transverse crest, and on the abdomen they are thinly disposed, and afford, in some parts, a view of the naked skin. The colour of the hair is blackish brown, more or less intense on every part of the body, except the crown of the head, a streak along the back and the extremity of the tail; these parts are white, with a slight tint of yellow; the mark on the head has a rhomboidal form, obtuse and rounded anteriorly, and gradually attenuated as it passes to the shoulders, where it unites with the streak on the back; in some individuals this streak is interrupted. On the abdomen the brown is of a lighter hue, inclining to greyish or rufous. The covering is subject to several variations; the tail is scarcely half an inch long, but the hairs covering it project above an inch from the body; the limbs are short and stout, and the feet agree in structure with those of the allied genera, being formed for the plantigrade manner of walking; the claws are united at the base by a thick membrane, which envelops this part as a sheath: those of the fore feet are nearly double the size of those of the hind feet. In place of the pouches and reservoirs of fetid fluids, with which several genera of this family are provided, the mydams has two glands of an oblong form, about one inch long and half an inch wide, near the extremity of the rectum; they are placed opposite to each other, and are individually furnished with an excretory duct nearly half an inch long, which communicates with the intestine. In the middle of each duct is a very minute aperture, surrounded by a muscular ring, somewhat swelled, which enables the animal at pleasure to discharge or retain the fetid fluid secreted by the glands. The ducts enter the rectum about half an inch within the external aperture. The internal surface of these glands is covered with numerous wrinkles disposed transversely; the fluid secreted by them is perfectly analogous, in its odour, to that secreted by several species of *Mephitis striata* of Fischer. Having experienced that of the latter, which is known in most parts of North America by the name of skunk, I readily recognised it in Java."

The distinctions between this animal and the mephitic animals of America are very striking. Its muzzle is lengthened like that of the badger, and the extremity is truncated and somewhat enlarged, so as to bear a slight resemblance to the snout of the hog. This elongation of the jaws, without any increase of the number of the teeth, or any enlargement of their size, gives a ragged appearance to the mouth of the animal, and indicates a corresponding feebleness in its bite. The shortness of the tail is another remarkable distinction, and so is the character of the external covering. On the American animals the hair, especially toward the hinder parts, is long and soft, and that on the tails of the whole is very much

produced. The hair of this one, on the other hand, is short all over the body and tail, and it is hard and stiff. In the others the neck and anterior extremities are rather more slender than the posterior parts of the animal, whereas in this one the neck is very thick and stout, and the fore legs are longer, as well as stronger, than the hind ones. The whole appearance, indeed, indicates a difference of habit in the animal, varying as much from the mephitic animals of America as these vary from the polecats and martens. For these reasons it cannot naturally be classed in the same group or family either with the one or the other, but must stand apart as an individual species in the system, having no generic and few family resemblances to any of the other mammalia.

The geography of the animal, as ably explained by Dr. Horsfield, is as peculiar as itself. In the low and fertile parts of Java there is not a vestige of it, and it has not a name in the language of those people who inhabit the parts of the island that may be strictly called tropical. It is a mountaineer, and, though inhabiting almost immediately under the equator, it inhabits a temperate climate. It is never found except at an elevation of more than seven thousand feet above the level of the sea, and at this great elevation it does not inhabit one continuous tract, but a number of detached places. The profile of Java, like that of many of the other volcanic islands in that part of the world, is very peculiar when viewed in its length. It does not present one great central elevation, to which all the hills and slopes are subordinate, as is the case with islands which bear evidence of being raised from the bottom of the sea *en masse*. It presents a succession of conical peaks, which rise high above the intermediate parts at the greatest elevations of these; and thus, if a traveller passes along the middle line of the island, he finds an alternation of climates and productions which contrasts very strongly with each other. Those elevations are the native place of the telogon, although it is not equally abundant on them all. On the steep conical peaks, which rise from the warm plains by continuous acclivities, it is comparatively rare; but where the ground at an elevation equal to, or greater than that which has been mentioned, expands into breadth, it is very abundant. Thus it is really an animal of the plains, although of those plains only which are on the mountain tops. There are many such plains in Java, and they bear nearly the same relation to the fertile but pestilent valleys on the shores, which the table land of Mexico does to the low and pestilent country on the west side of the Gulf.

With European settlers, and also with the Chinese, these are the favourite places of Java, for permanent residence, even by those whose business is on the sea-coast. They are very healthy and very pleasant, and they admit of the cultivation of wheat and other European grain, and also of many fruits and culinary vegetables, while they are totally unfit for the growth of rice, the staple and almost the only grain of the low districts. These circumstances give Java, notwithstanding the extreme insalubrity of its shores, considerable advantages over India, and indeed over most of the warm countries in the East; inasmuch as a congenial climate may be found for the inhabitants of almost every latitude on the face of the earth; and if a European chooses his residence high enough, he may enjoy a temperate climate, and one which is healthy and salubrious all the year round. The telogon,

as we have said, is very numerous in those plains, and it is often particularly annoying to the cultivators, from the facility which it has in rooting up the ground, and the offensive odour which it gives out when annoyed. The name telogon was given to it in consequence of the angle at which the nose is truncated off, which is nearly the same as that in the hog, and of itself would indicate not merely an animal which burrows in the ground for its dwelling, but one which turns up the earth in search of its food. In the plantations of the cultivators it destroys the roots of the young plants, and thus produces much greater waste than a larger animal feeding only upon full-grown vegetables. So great are the depredations which it commits, that in some districts the inhabitants live in considerable dread of its visitations. It inhabits the rich black soil only, and lives under ground during the day, but comes abroad in the night, and leaves very decided marks of the laborious working of so comparatively small an animal. Its lodging is generally concealed under the roots of a tree. It is of a circular form, several feet in diameter, and worked firm and regular on the inner surface. The entrance is by a subterraneous passage two or three yards in length; and the animal is at some pains in concealing the opening to this by leaves, grass, and other vegetable matters. These animals are not social, but they live in pairs, and we believe the pairing is permanent, continuing intermediate between the broods. The litter is not understood to consist of more than two or three; but it is not correctly ascertained how many litters are produced in the year, or whether there are more than one.

Besides the roots of plants, these animals eat a vast number of earth-worms, which are both abundant and of large size in the rich upland plains of Java; and it is highly probable that its chief use in wild nature is to regulate the numbers of those worms, because it is found only in grounds where they are abundant. It is not very probable that it feeds on birds, and its mouth is not well adapted for contending with any of the mammalia. The fore teeth in the lower jaw stand out nearly as a continuation of the jaw itself, and thus are incapable of biting anything which is hard or tough; and the canines are also small and feeble. In every part of its character, therefore, this is a most singular animal, and an animal adapted to a singular locality.

We shall close our account with another very short extract from Dr. Horsfield, descriptive of its manners, not as tamed, but as kept by him in temporary captivity. "The mydaus," says he, "is not ferocious in its manners, and taken young, like the badger, it might easily be tamed. An individual, which I kept some time in confinement, afforded me an opportunity of observing its disposition; it soon became gentle, and reconciled to its situation, and did not at any time emit the offensive fluid; I carried it with me from Mountain Prahee to Bladeran, a village on the declivity of that mountain, where the temperature was more moderate. While a drawing was made, the animal was tied to a small stake; it moved about quietly, burrowing the ground with its snout and feet, as if in search of food, without taking notice of the bystanders, or making violent efforts to disengage itself; on earth-worms (*lumbrici*) being brought, it ate voraciously; holding one extremity of a worm with its claws, its teeth were employed in tearing the other; having consumed about ten or twelve, it be-

came drowsy, and, making a small groove in the earth, in which it placed its snout, it composed itself deliberately, and was soon asleep."

With this quotation we shall close our notice of the telagon, and also of the very interesting family of animals to which it belongs. Next to the cat and dog tribes, the martens are the most interesting of all the mammalia, on account of the exertion which they require to make use of in finding their food, and of the development of the sentient or animal part of their structure which this requires. In some respects they are superior to either of those families which we have named; for they have more courage and more strength in proportion to their size, and they are furnished with clothing which protects them better against the vicissitudes of the seasons, and especially against the rigour of winter in those climates where the winter is more than usually severe.

MARVEL OF PERU is the *Mirabilis dichotoma* of Linnæus, a tuberous-rooted South American ornamental plant, introduced to our gardens nearly two hundred years ago. It belongs to the natural order *Nyctagineæ*.

MASON BEES, MASON WASPS, &c. These terms are applied to those solitary species of bees and wasps which construct their nests of bits of earth and sand. Of these, the genera *Anthophora* amongst the bees, and *Odynerus* amongst the wasps, are the most remarkable. We have, however, given an account of the proceedings of these insects in other parts of our work.

MASTICH TREE is the *Pistacia Lentiscus* of Linnæus, a tree indigenous to the South of Europe and opposite coast of Barbary. This tree yields the true mastic of commerce, its sap being obtained by wounding the bark.

MATHIOLA (R. Brown). A genus of beautiful flowering annual, biennial, and perennial herbs and undershrubs, natives of different parts of the world. They belong to *Cruciferae*, and are known by the name of stock, or gillyflower, needing no description.

MAURANDYA (Jacquin). A genus of Mexican climbers, bearing didynamous flowers, and belonging to *Scrophularinæ*. They are greenhouse plants, thrive in any light rich soil, and are readily increased by seeds or cuttings of the young shoots planted under a striking-glass. The hardiest and most showy is the *M. Barclayana*.

MAURITIA (Linnæus, fil.) A genus of palms indigenous to South America. They are of lofty growth, and when kept in our stoves require a rich sandy loam, and plenty of water when growing freely.

MAXILLARIA (Flora Peruviana). A genus of South American orchideous plants, some of them bearing splendid flowers. They are managed like their congeners the epidendrons and oncidiums, and kept in a warm damp stove.

MAY APPLE is the *Podophyllum peltatum* of Linnæus: the duck's-foot of North America. In our gardens it is cultivated in a rich soil, and increased by dividing the roots or by seeds.

MAY FLY. The name given to a species of neuropterous insects of not very definite significance; being by some authors given as identical with the *Ephemera vulgata*, by others as a species of *Phryganea*, and by others as the *Sialis nigra*, which, appearing in the month of May, and serving as a bait for fish, seems more particularly entitled to the term.

MEADOW GRASS is the *Poa pratensis* of

Linnæus, one of the most common of our agricultural grasses, and found in every pasture and meadow in the kingdom.

MEADOW RUE is the *Thalictrum flavum* of Linnæus, a British plant, and sometimes met with in gardens.

MEADOW SAFFRON is the *Colchicum Byzantinum* of Linnæus, a celebrated medicinal plant. The *C. autumnale* is a British plant, and is sometimes cultivated by farmers.

MEADOW SAXIFRAGE is the *Saxifraga* of Linnæus; a genus of annual, biennial, and perennial herbs, mostly natives of Europe—uncultivated.

MEADOW SWEET is the *Spiræa ulmaria* of Linnæus, a common British plant, often met with on the banks of rivulets.

MEAL WORM. The scaly cylindrical larva of the coleopterous insect *Tenebrio Molitor* (see *TENEBRIONIDÆ*) is thus named, from taking up its residence in flour, meal, cakes, sea-biscuit, &c., in which it does great damage, by eating or gnawing it in pieces. It is upwards of an inch long, and furnished with short but powerful jaws, and remains two years in the larva state, previous to becoming a pupa. It is especially destructive in barrels of biscuits on board of ships.

MEDICAGO (Linnæus). An extraordinary genus of annual and perennial herbs, mostly natives of Europe. The flowers are diadelphous, and belong to the natural order *Leguminosæ*. The hop-trefoil and lucern, both agricultural plants, belong to this genus.

MEDLAR is the *Mespilus germanica* of Linnæus, a well-known inferior fruit-tree, frequently cultivated in gardens, and also found wild in many places in England and on the continent. They are commonly grafted or budded on the common hawthorn, and thrive well in any soil or situation.

MEDUSA is the *Euphorbia Caput Medusæ* of Linnæus, a grotesque growing species of spurge indigenous in Africa. It is a greenhouse undershrub and succulent.

MEGACHILE (Latreille). A genus of long-tongued bees, (family *Apidae*, sub-family *Dasygastre*, or woolly-bellied,) having the abdomen of an oval form, densely clothed on the under surface with hairs, which form in the females a pollen brush, and flattened above. The maxillary palpi are composed of only two joints. The abdomen, moreover, is capable of being turned upwards, so as to enable the bees to make use of their sting above the surface of the body. These insects are generally called leaf-cutter bees; and the instinctive agility with which they contrive to clip off circular pieces from the leaves of rose-trees and other shrubs with their jaws is most extraordinary: these pieces of leaves are employed in the construction of their nests; and it is curious to perceive one of these bees flying off with a piece of a leaf as large as, or larger than, its own body. Their nests are formed in the crevices of walls, or in burrows in rotten wood; and the cells are lined at the bottoms and sides with the pieces of leaves, which are cut exactly to fit each other; a supply of pollen paste is then introduced into the cell, together with an egg, and the whole is closed by several layers of circular bits of leaf, the uppermost of which forms the floor of the next superincumbent cell, which is similarly constructed; and so on, cell after cell is added, until the burrow is completely filled. The manner in which the bee contrives to cut off a bit of the leaf

deserves particular notice. Reaumur, to whom we are so much indebted for our knowledge of the proceedings of insects, thus describes it:—When the female bee has chosen a leaf, she alights upon it, sometimes taking her station on its upper surface, sometimes underneath it, and at others upon its edge, so that the margin passes between her legs. Her first attack, which is generally made the moment she alights, is usually near the footstalk, her head being turned towards the apex. Now and then, however, she places herself near the apex, facing the footstalk. As soon as she has made a beginning, she continues cutting with her jaws, (which are admirably formed for the purpose,) and without intermission, till she has finished her work. As she proceeds, she keeps the margin of the detached part between her legs, those of one side being above and the other below it, so that the section keeps giving way to her, and does not interrupt her progress. She makes her incision in a curve line, approaching the rachis first; but, when she has reached a certain point, she keeps receding from it towards the margin, still cutting in a curve. When she has nearly detached the portion she has been employed upon from the leaf, she balances herself upon her wings, lest its weight should carry her to the ground, and the very moment it parts from the parent stock she flies off with it in triumph, the detached portion remaining bent between her legs, and being perpendicular to her body.

There are seven or eight British species belonging to this genus, of which the *Apis centuncularis* of Linnaeus may be regarded as the type; they are generally about equal in size to the working hive-bee, which they much resemble in their outward appearance. Of these species the habits of all have not been observed, nor is it known that all are leaf-cutter bees, although from the structure of the mouth it is most probable. But there are several other bees nearly allied to these, but differing in certain structural peculiarities, and belonging to the genus *Osmia*, which are also leaf-cutters, or upholsterers, as they have been called, and including a species respecting which a good deal of discussion took place, first observed by Reaumur, and which employs the leaves of the scarlet poppy for the linings of its cells. Some species of *Megachile* have also been called carpenter bees, from making their nests in rotten wood; whilst one of the largest species, *Megachile muraria*, a native of France, Germany, &c., is a mason bee, forming its nest with very fine earth, which it kneads into a kind of mortar, and which is placed against the sides of walls exposed to the sun, and which contains twelve or fifteen cells.

MEGASTACHYA (Beaunois). A genus of annual and perennial grasses, mostly tropical, but much more curious than useful.

MELALEUCA (Linnaeus). A genus of green-house trees and shrubs, chiefly natives of New Holland. The flowers are polyandrous and handsome, and the plants associate with *Myrtaceæ*. They are successfully grown in sandy loam and moor earth, and are propagated by cuttings in the usual way.

MELAMPYRUM (Linnaeus). A genus of British annual weeds, commonly called cow-wheat. They belong to *Scrophularina*.

MELANDRYIDÆ (Leach; *SERROPALPIDES*, Latreille). A family of coleopterous insects, belonging to the section *Heteromera*, and sub-section *Stenelytra*, Latreille, having the maxillary palpi large,

deflexed, and strongly serrated; the antennæ are inserted in a notch on the inside of the eyes, and are short and filiform; the body is generally oblong or narrowed, and subcylindric, the mandibles notched at the tip, and the tarsal claws simple; the head is deflexed and small, the thorax trapezoid, the posterior legs simple, and the mouth not rostrated; by which characters they are distinguished from the *Cistelidæ*, *Helopidæ*, *Edemeridæ*, and other heteromorous *Stenelytra*. The penultimate joint of the tarsi is generally bilobed; in some, however, it is entire, and in these the hind legs are saltatorial; the anterior tarsi are short and dilated. These insects are of a small, or but moderate size, and are found either beneath or upon the bark of trees; they are generally of obscure colour, more or less varied with fulvous. The genera which Stephens introduces into this family are *Lagria*, *Melandrya*, *Hollomenus*, *Scraptia*, *Phloiotrya*, *Dircæa*, *Hypulus*, *Abdera*, and *Orchesia*, the first of which forms, according to Latreille, a distinct sub-family. In the genus *Melandrya* the maxillary palpi are serrated, the tips of the second and third joints being internally produced into a point; the thorax is abruptly depressed at the sides near the posterior angles, with the posterior margin sinuated. The scutellum is of the ordinary size. There are two British species, *Mel. caraboides*, being the type, of a blue black colour, and not of uncommon occurrence. It is very active, and flies well.

MELANIA (Lamarck; *HELIX* AMARULA, Linnaeus). This genus of shells was blended by Linnaeus with the *Helices*, and some authors have supposed it to possess some affinity to the *Lymnaea*; but except their both being fluviatile molluscs, and the form of the spire in the *Melania* an oblong oval, with the spire produced or turreted, they are in other respects very dissimilar. The *Melania* is closed by a horny operculum; they are rather thick, the exterior wrinkled, and the margin of the spiral whorls often surmounted with spines or knobs; the columella arched and smooth; the lower part of the aperture entire, constantly wider than the upper; they are also covered with a brown or black epidermis. Their habitat is India, Africa, and the two Americas. Many species are found in a fossil state. They belong to the third family *Ellipsostomatæ*, of the second order *Asiphonobranchiata*.

MELANOPSIS (Lamarck). These molluscs are fluviatile, and are very nearly allied to the *Melania*, from which, however, they may easily be distinguished, by their columella being callous at the upper part, and their base truncated, as in the *Achatina*. They approximate the *Pirena*, from which they principally differ in having only one sinus, or a widened opening at the base of the shell. They are turreted, the aperture entire, oval, and oblong; the columella callous at the upper end and truncated at the base; the right side with a sinus; they possess a horny subspiral operculum. Ten fossil species are described. This genus belongs to the second family *Entomostomatæ*, first order *Siphonobranchiata*, second class *Paracephalophora*.

MELANTHACEÆ. A natural order of plants, comprising above twenty-two genera, and at least one hundred and twelve species. They are mostly bulbous or tuberous rooted plants, and occur in all the four quarters of the globe. They range next to *Tulipaceæ*, but they are inferior to them in the grandeur of their

flowers. A dangerous and poisonous acrid juice is detectable in many of them, particularly *Colchicum* and *Veratrum*. The roots of the former are the basis of the *eau medicinale*, and are now used in cases of gout with much success. The root of the *Veratrum* is believed to have been the hellebore of the ancients, an active drug, but requires to be administered in small doses. The other genera in this order are:—*Bulbocodium*, *Merendera*, *Uvularia*, *Disporum*, *Scheuchzeria*, *Burckhardtia*, *Anguillaria*, *Ornithoglossum*, *Androcymbium*, *Melanthium*, *Wurmbea*, *Tofieldia*, *Xerophyllum*, *Helonias*, *Nolina*, *Leimanthium*, *Chamaelirium*, *Peliosanthes*, *Lichensteinia*, and *Zigadenus*.

MELASIS (Olivier). An interesting genus of coleopterous insects, belonging to the section *Pentamera* and family *Buprestidæ*, but receding from the typical character of the family, having the antennæ strongly pectinated in the males and serrated in the females; the tarsi are subcylindrical, the body cylindrical, the palpi terminated by a large globular joint, and the posterior angles of the thorax acute, in several of which respects this genus seems to form the connecting link between the two great families *Buprestidæ* and *Elateridæ*. There is but a single British species, *Mel. buprestoides*, Olivier, of a brown colour, not shining, and with reddish antennæ and legs. Found but rarely in the New Forest, &c.

MELASPHORULA (Ker). A genus of bulbous herbs from the Cape of Good Hope, belonging to *Triandria Monogynia*, and to the natural order *Iridææ*. Generic character: spathe two-valved, herbaceous, spreading; corolla of six petals, spreading, pointed; stamens ascending; stigma recurved; capsule turbinate; seeds small and globular. These plants succeed with the same management as *Iris* and other Cape bulbs.

MELASTOMACEÆ. This order contains twelve genera and above seventy-six species of plants. They are in general handsome shrubs or trees, and leaves with several costæ, that is, with the midrib subdivided, and running longitudinally along the disc of the leaves. To be grown well, they require much heat and much space, in order that the foliage and flowers may assume their proper magnitude. The fruit is generally a fleshy insipid juicy berry, for the most part eatable, and of so deep a black as to dye the teeth and mouths of the eaters; hence the name *Melastoma*, or black-tooth. The juice is sometimes, as in *M. Toccia*, of so intense a black as to be used instead of ink. The leaves, and indeed all parts of the *M. parviflorum* and *M. longifolium*, afford a black dye, and, as well as those of the *M. malabathrica*, are used for dyeing cottons. The leaves of the *M. theaxans* are used at Popayan instead of tea, and are said to form a beverage preferable to that afforded by the Chinese tea-plant. This shrub is hardy, and might be cultivated in many parts of Europe.

The macaco-wood of commerce is the wood of *Tococa Guianensis*, the fruit of which is considered an agreeable food by man, and very much relished by monkeys. The fruit of *Blakea triplinervis* is yellow, and by most persons thought not only eatable, but pleasant.

Most of the *Melastomaceæ* thrive in moor-earth, and are propagated readily by cuttings. They must not be over-watered in winter.

MELEAGRA (De Montfort). A genus of molluscs now forming a subdivision of the genus *Turbo*.

MELEAGRINA (Lamarck; *MYTALUS MARGARITIFERUS*, Linnæus). A very great affinity doubtless exists between this mollusc and the genus *Avicula*, with which De Blainville has reunited it; but we trace distinctions sufficiently marked to induce us to preserve it as a separate genus, though contrary to the opinion of that eminent naturalist. The shell is always equivalve, always without the elongated transverse base, without the cardinal tooth, and the form of the shell constantly orbicular, sometimes attaining eight inches in diameter. In addition to these striking differences, the sloping sides of the opening, admitting the passage of a byssus, is very perceptible on both valves, which never occurs in the *Avicula*, where a notch answers the same purpose. The exterior of the valves is less smooth, and generally covered with scale-like imbrications, the terminations of previous stages of growth.

It is from this mollusc that the highly coveted jewel, the pearl, is extracted, which, under the article **PEARL**, will be more amply described; and from the valves of the *M. margaritifera*, the type of that genus, commonly called the Mother-of-Pearl Oyster, numerous elegant trinkets and ornaments are fashioned by the skilful artist. In China these shells are most abundant, but they do not yield so fine pearls as those in the Persian Gulf and other parts of the East. The valves, nevertheless, constitute an important branch of commerce, and ships of large burthen have brought them to England in such quantities that they formed a portion of the vessel's ballast. See **AVICULA**.

MELECTA (Latreille; *CROCISA*, Jurine). A genus of long-tongued bees, belonging to the family *Apidæ* and sub-family *Cuculinæ* (which see), having the body ornamented with patches of hairs of a white or silvery colour, the wings with three complete cubital or submarginal cells; the paraglossæ, or lateral divisions of the labium, nearly as long as the palpi, and the maxillary palpi five or six-jointed. The species are amongst the handsomest of our indigenous bees, and are parasitic in the nests of the species of *Anthophora* and some other mason bees, about the entrances of which they may be observed flying in company with the real architects of the nests, which seem to take no notice of the presence of these their enemies. It has been generally considered that we possessed but a single British species of this genus, *M. punctata*, Villars; but Mr. Newman has lately published the description of six species in the tenth number of the Entomological Magazine, which, however, we believe are considered merely as varieties of the common species.

MELHANIA (Torskald). A genus of tropical trees, two of which are the red-wood and black-wood of St. Helena. The flowers are monadelphous, and the genus is ranked in the natural order *Byttneriaceæ*. These exotics are kept in our stoves, and potted with loam and moor-earth, but are very subject to be preyed on by insects, which, if suffered to remain, prevent their growth.

MELIACEÆ. A natural order of plants containing fourteen genera and thirty-five species. The type of the order is the *Melia Azedarach*, or bead-tree, a native of Syria. The order is particularly distinguished by the stamens being united into a tube bearing the anthers; the leaves are usually pinnated, and most of the species, which are all either trees or shrubs, are natives of tropical forests. The fruit of

some of the species is poisonous, but the bark of several is employed medicinally in countries where the plants are found wild. The order contains the following genera, viz., *Turraa*, *Quivisia*, *Sandoricum*, *Melia*, *Trichilia*, *Ekebergia*, *Guarea*, *Heynea*, *Cedrela*, *Swietenia*, *Chloroxylon*, *Flindersia*, *Carapa*, and *Walsura*.

MELIANTHUS (Linnæus). A genus of evergreen shrubs, natives of the Cape of Good Hope. The flowers are didynamous, and are ranged in the order *Rutaceæ*. They are common in every greenhouse, easy of cultivation, and readily propagated by cuttings.

MELICA (Linnæus). A genus of grasses, two of which are natives of Britain, where they are called melic-grass. They are not economical plants.

MELICHRUS (R. Brown). A pretty genus of evergreen shrubs from New Holland. The flowers are pentandrous, and belong to the natural order *Epacridæ*. They thrive in loam, sand, and moor-earth mixed, and cuttings of the young shoots strike root readily.

MELICOCCA (Linnæus). A genus of tropical fruit-trees called in this country honey-berries. The flowers are octandrous, and the plants belong to *Sapindaceæ*. The fruit is almost black, but very sweet and pleasant. They succeed very well under ordinary stove management.

MELILOTUS (Tournefort). A genus of annual, biennial and perennial herbs belonging to the *Leguminosæ*. The melilots are very similar to the clovers, with which they were once generically combined. *M. officinalis* was formerly used as a medicine, as an ingredient in plaisters, poultices, and emollient fomentations. It has a strong smell and bitter taste; but notwithstanding both, some cattle are fond of it. The celebrated Gruyère cheese owes its peculiar flavour to the seeds and flowers of this plant. The flowers are much resorted to by bees, and hence it has been called the honey-lotus.

MELISSA (Linnæus). A genus of well-known garden herbs, commonly called balm, of which there are five species. They belong to the natural order *Labiata*.

MELITTA (Kirby). Under this name Mr. Kirby, in his invaluable Monograph on the English Bees, separated those species which have the lower lip, or tongue, as it is called, very short, and which have subsequently been formed into the family *Andrenidæ*, (which see.)

MELITTIS (Linnæus). A genus of plants called bastard-balm, found plentifully in British woods. It also belongs to *Labiata*.

MELLIFERA—Honey-collectors (Latreille). A sub-section of aculeate hymenopterous insects, corresponding with the Linnæan genus *Apis* (see the articles *BEES*, *APIDÆ*, *HYMENOPTERA*, &c.), divisible into the two families *Andrenidæ* (*Melitta*, Kirby), and *Apidæ* (*Apis*, Kirby).

MELOCACTUS. Is the *Cactus Melocactus* of Linnæus, commonly called the turk's-cap or melon thistle.

MELOCHIA (Linnæus). A genus of tropical undershrubs, bearing monadelphous flowers, and belonging to the natural order *Byttneriaceæ*. They are stove plants, and easily propagated by cuttings.

MELOE (Linnæus). A genus of coleopterous insects belonging to the section *Heteromera* and family *Cantharidæ*, having the body large and distended,

the wings entirely wanting, and the elytra short, oval, and folding partially over each other at the base; the antennæ are eleven-jointed, of nearly equal thickness throughout, or dilated and singularly knotted or elbowed in the centre, especially in the males. These insects are of a comparatively large size; they are very inactive, crawling on the ground or amongst low herbage, upon which they feed; they emit an oleaginous liquid from the joints of the limbs, when disturbed, of a yellow colour and disagreeable odour. They are found in spring, and some of the species, especially the type *Meloe proscarabæus*, are sufficiently common. They possess in some degree the vesicatory powers of the *Cantharides*, and are indeed employed in some parts of Spain in lieu of the real blister fly. From this circumstance Latreille has conjectured that they were identical with the ancient *Buprestis*; but this can scarcely be, as they do not agree with the description of that insect, which is said to have resembled a wasp. The early history of these insects has been the subject of much discussion amongst naturalists, and may be cited as an example of the comparatively great extent of our ignorance of the real history of these tribes, and with the hopes of inciting persons who feel an interest in entomology to look at insects with a different eye than that of mere collectors. According to Gødart and De Geer, the female meloe digs into the earth, and there deposits a mass of yellow eggs, from which, in due time, the larvæ are excluded, which are described as having six legs, two antennæ, and two long threads at the extremity of the body. These larvæ have never been observed above one eighth of an inch in length, and the most curious portion of their history is, that they fasten themselves upon the bodies of bees and flies, and suck their juices. Kirby and Leon Dufour, however, regarded these supposed larvæ as apterous insects, belonging to the order *Parasita* or *Anoplura*, the former naming them *Pediculus Melittarum*, and the latter even establishing a distinct apterous genus for their reception, *Triungulinus*. Since this period, however, several observers have endeavoured to solve the difficulty, the most recent being Mr. E. Doubleday, from whose pleasant paper in the Entomological Magazine the following quotation is derived:—"It is but rarely that we see a meloe in this neighbourhood (Colchester), but after diligent search, I found a few *Proscarabæi* of both sexes. These I placed on some light earth, under a bell glass, giving them plenty of ranunculus leaves to feed upon. The females, in particular, fed well, and grew wonderfully large in the abdomen; therefore I felt sure that I should soon have lots of good eggs, and then of course lots of larvæ, which would not be mere *Acaridæ* (*Pediculidæ*), but *bonâ fide* young meloes. One morning I found that something particular was going on amongst them. The old ladies, no doubt with much exertion, had scooped out places in the earth wherein to bury their eggs, and soon after a lump of bright orange eggs, about the size of a Palma Christi seed, was deposited in each, and carefully covered over. This was just what I had expected from what I had read about this matter. I now set the mould aside, keeping it a little moist, and covered up so that nothing could get at it. Thus it remained for about two months, when out sallied a host of little animals of a light brown colour, having, as near as may be, the shape of Kirby's figure in the *Mon. Apum*, which ran about the glass as swift as a

Yankee pony*, allowance being made for their difference in size. If I am not much deceived, I saw some of them actually making their way through the egg-shell. I put a lot of them into a glass jar, with some ranunculus leaves and some flies, principally *Syrphi*, and *Musca*; to these latter they soon attached themselves, just at the base of their posterior legs, remaining fixed so long as their victims lived. I supplied them with fresh food for some days, but with all their feeding they grew none the bigger, and in about three weeks they were all dead. A friend of mine, not an entomologist, but a lover of natural history, has since told me that he tried to rear the larva from the egg, but met exactly with the same fate as myself." Of the fact, then, that the *Triunglinus*, as it has been called, issues from the egg of the meloe, there is abundance of evidence; and hence, taking it for granted that these little active animals are the real larvæ of the meloe, Latreille and some other recent authors (including Drs. Brandt and Erichson, who have lately published a valuable monograph upon the genus in the *Nova Acta Naturæ Curiosorum*) have endeavoured to account for the curious circumstance connected with its economy, by considering that it attaches itself to bees in order to be by them carried into their provisioned nests, where, like some of the other genera of *Cantharidæ*, it is supposed to attach itself parasitically to the larva of the bee. It must be admitted, however, that this is but conjecture, and that direct observation is needed as to the matured state of the larva and pupa.

Mr. Stephens has divided the British species into two genera, from the structure of the antennæ; but if this character were allowed to influence the generic distribution of this group, there would be a great number of similar groups required. There are nine British species, including the type *Meloe proscarabæus* (Linneus), *Proscarabæus vulgaris* (Stephens), which is of a black colour, shining and punctured, with the sides of the head, thorax, antennæ, and legs, violet. The elytra are slightly rugose. It is advisable that chemical experiments should be made, to ascertain the medical properties of these insects.

MELOLONTHIDÆ (MacLeay). A family of *Coleopterous* insects, belonging to the section *Pentamera*, and sub-section *Lamellicornes*, having the upper lip composed of a transverse plate, and generally deeply emarginate beneath. The mentum is as long as, or longer than, wide, somewhat narrowed in front. The maxillæ are horny and truncate at the extremity, with several (generally five or six) strong teeth; the legs are slender, and the tibiæ rather narrow; the antennæ nine- or ten-jointed, and terminated by a large lamellated club, varying in the number of its joints from three to seven, and the plate being very large in the males of the typical species; the body is oval and sub-convex; the elytra shorter than the abdomen, and the clypeus divided by a strong suture in front of the eyes.

This is a very extensive family, comprising many handsome species, which cannot, however, vie in splendour with the *Cetoniidæ*. In the perfect state these insects are eminently phyllophagous, that is, feeding upon the leaves of trees, for which the struc-

ture of the mouth is conveniently adapted, the maxillæ, as represented in our article *INSECT*, p. 853, fig. 105, being fitted for cutting the leaves by their confined action, whilst the internal basal structure of the mandibles, fig. 97, p. 852, are equally adapted for chewing them when cut. It is, however, in the larva state that these insects are most especially injurious to the agriculturist and horticulturist, feeding upon the roots of various plants; and as they remain three or four years under the latter form, and acquire considerable size, it may be easily conceived that in seasons when they abound, they are capable of inflicting real injury.

Of these insects, the most common is the cockchafer, constituting the type of the family, and which, from our earliest years, we have been taught to look upon as one of the most despised of the insect tribes; and yet this insect, in several interesting particulars, is not behind many of its more showy brethren. The peculiar structure of the mouth, the very beautiful fanlike antennæ of the males, and the curious pointed extremity of the body, through which children are in the cruel practice of running a pin, round which the insect whirls in its endeavours to escape, are characters which ought to rescue these insects from the tortures which are inflicted upon them, even without any regard being paid to their natural history. It is advisable, indeed, that means should be resorted to for the destruction of these insects when they happen to abound to an injurious extent; but this ought surely to be effected in the most summary manner. During the day they remain inactive in the trees and hedges; but no sooner is the sun set, than they emerge from their retreats, and fly, humming, round the trees, in search of their mates. Their existence in this state is but short, and their motions exhibit but little energy; they fly with heaviness and irregularity, and strike at whatever object may happen to be in their way. After coupling, the male soon dies, and the female deposits her eggs in the ground, digging six or eight inches into the earth. At times, and in favourable seasons, these insects swarm to a very great extent; and there are various statements on record, in which their numbers are described as incredible, and the damage which they committed not yielding to that caused by the locust. Of these accounts perhaps the most remarkable is that given in one of the early volumes of the *Philosophical Transactions*, by Mr. Molineux, in which their appearance in certain districts in Ireland is narrated. They were first noticed in Galway, and thence penetrated inland towards Heddford. They were seen in the daytime hanging from the boughs in clusters, like bees when they swarm, dispersing towards sunset "with a strange humming noise, like the beating of distant drums, and in such vast numbers that they darkened the air for the space of two or three miles square. In a short time they entirely ate up the leaves, stripping the trees as bare as in the depth of winter; they also entered the gardens, and attacked the fruit trees in the same way. Their multitudes spread so exceedingly that they infested houses, and became extremely offensive and troublesome. Their numerous young also, when hatched, did still more damage than all the swarms of the perfect beetle, eating up the roots of corn and grass. This plague was happily checked in several ways. High winds and wet mizzling weather destroyed millions of them in a day; and during this weather the swine and poultry watched under the trees for

* Your readers cannot fail to recollect the "very severe pony," which was chased three times round a field by a flash of lightning which at last gave up the pursuit, "not being able to come within a rod of it."

their falling, and fed and fattened upon them; and "even the poorer sort of the country people, the country then labouring under a scarcity of provisions, had a way of dressing them, and lived upon them as food." Smoke also was employed, and by burning heath, fern, &c., the gardens were partially saved. And Mouffelt, in his Theatre of Insects, informs us, that in 1574 so great a number of cockchafers were driven into the river Severn that they hindered the mills from working, and were with difficulty destroyed by the united efforts of the people, and the different kinds of hawks, ducks, and other birds, which devoured them with eagerness. In 1751 also the county of Norfolk suffered greatly from their ravages, a great many crops being totally destroyed by these voracious insects. Various plans have been proposed for their destruction when they happen to abound. Torches held for a few minutes under the bushes stupify them, and they fall to the ground on beating the bushes with a stick, when the cockchafers are collected and killed. Children are also employed to follow the plough and collect the larvæ, or white worms as they are called, as they are turned up. This, however, can only be done at certain seasons of the year, and after the end of the autumn it would be ineffectual, as the larvæ burrow deeper into the ground to avoid the rigour of winter. Pigs and poultry may also be similarly employed, and rooks are too well aware of the dainty treat which awaits them to be far behind the plough; they will also even pull up the dead roots of grass where the larvæ harbour; and hence they are mistaken by ignorant persons for the real cause of the mischief, and scarecrows are placed to drive these useful auxiliaries away, of which an instance is given by Mr. Spence, in the Introduction to Entomology, who endeavoured to convince one of these self-willed farmers that the rooks were his friends but who only replied that "he couldn't bear to see d' nasty craws pull up all d' gress, and see he'd set d' bairns to hing up some ad clouts to flay em away. Gin he'd letten em alean they'd sean hev reated up all d' cloze." The planting of various vegetables to which they are more especially partial, in the neighbourhood of plants which it is desirable to preserve, and the spreading of soot around the roots of the latter, have also been suggested, but the benefit resulting from these modes must be very partial, even if they could be adopted to any extent. The most advisable plan, as suggested by the abbé Rosier, is to keep a strict search for the insects for several seasons, by children and women, and to destroy as many of them as possible, and as soon as they make their appearance. The larvæ of these insects are thick carved fleshy grubs, differing so slightly from those of the *Cetonidea*, of which we have given a figure, that a more minute description may be dispensed with. At the commencement of the spring they quit their winter retreats at a depth in the earth, and come within a few inches below the surface of the ground; and when full grown, at the end of the summer of the third year, they again descend to the depth of two feet, where they become pupæ, having previously constructed an oval cell, very smooth on the inside. In the month of February, or even earlier, they assume the perfect state, but remain for a considerable time in a weak state, not venturing into the air until the fine days of May or the beginning of June.

The genera belonging to this family of insects are numerous, including *Melolontha*, *Amphimalla*, *Serica*,

Omaloptia, *Hoplia*, *Anomala*, *Anisoplia*, all of which are British; *Dephu cephalæ*, *Euchlora*, *Monochela*, and numerous other exotic genera, of whose habits no particulars have been furnished.

The genus *Melolontha* is distinguished by its ten-jointed antennæ, having the club of the male seven-leaved, and that of the female six-leaved. There are three British species, 1. *Mel. Fulva*, a large species, handsomely mottled with white, on a dark brown ground, found but very rarely on the coast of Kent, and by some authors considered as a species which only accidentally finds its way from the opposite coast of France. 2. *Mel. vulgaris*; the common cockchaffer, brown tree beetle, blind beetle, chaffer, Jack Horner, Jeffry cock, May bug, brown clock, dor, miller, acre bob, May bob or oak web, as it is variously termed in different parts of the country; and 3. *Mel. Hippocastani*, Fabricius. See Steph. Ill. Maud. vol. v. 412.

The June bug or fern web, *Melolontha solstitialis*, is of small size, and belongs to the genus *Amphimalla*, Latreille, having the antennæ only nine-jointed.

MELON. Is the *Cucumis Melo* of Linnæus, a well-known cultivated fruit belonging to *Cucurbitaceæ*.

The melon is chiefly cultivated in hotbeds or in pots, and requires a considerable degree of skill and incessant attention to grow it in perfection. The gardener's aim is to have ripe fruit about the first of June, to do which requires the constant labour of at least three or four months.

The varieties of the melon are numerous; but very few of them are worthy of cultivation, the larger varieties being particularly deficient in flavour. Mr. Knight recommends the green fleshed and Salonica or white fleshed variety. The seeds of the melon should be sown early in March, in middle-sized pots, previously netted with hay so as to secure the removal of the entire ball; a rich, sandy, and adhesive loam is placed upon the hay, and a single seed planted in each pot, which is then plunged to the rim in a moderate hotbed. In April the plants will be ready for transplanting, with the ball entire, either into the frame or into a larger pot, at least ten inches broad as the rim, if it is intended to fruit in one; this pot being first filled with a soil composed of five parts of chopped turf with its herbage, and one part of the recent poultry dung well incorporated together. About the beginning of June the fruit, if successful, will have attained a considerable size; but it requires very great care and skill to ripen it before the month of August. Great care should be taken to water the plant at the roots whenever the soil becomes dry, or the leaves begin to droop.

MELONIA (De Blainville; MELONITES, Lamarck). A fossil mollusc of microscopic size, classed by Fichtel with the *Nautili*.

MELYRIDÆ (Leach). A family of coleopterous insects belonging to the section *Pentamera*, and subsection *Serricornes*, having the palpi short and filiform; the mandibles emarginate at the tips; the body generally long and narrow, with the base of the head concealed by the broad shield-like and sub-convex thorax; the tarsal joints are entire, with the claws unidentate or margined with membrane; the antennæ are serrated and pectinated in the males of some species. The species are of small or moderate size; they are very active, elegantly coloured, and are found upon the flowers or leaves of plants, where they evidently subsist upon other insects which frequent the same situations. The family is but of small extent,

comprising the genera *Malachius*, *Aplocnemus*, and *Dasytes*, which are British, and *Lygia*, *Melyris*, and *Pelecophorus*, which are exotic; the typical genera *Melyris*, Fabricius, having the antennæ short and gradually enlarged to the tip, and being composed of several African species, the type being *M. viridis*, a common species inhabiting the Cape of Good Hope.

MEMBRACIS (Fabricius). A curious genus of exotic homopterous insects, belonging to the first section of the family *Cercopidae*, and having the anterior tibiae dilated, the scutellum not developed, the body being covered above by the large semicircular prothorax, which is elevated like the top of a helmet, and is not thicker than a card; there are numerous species, all of them inhabiting South America.

MEMECLYON (Linnæus). A genus of Indian trees, one of which bears edible fruit. They belong to the class *Octandria*, and to the natural order *Melastomaceæ*. They grow readily in our stoves, and may be propagated by cuttings. These plants have been separated from *Melastomaceæ* by M. De Candolle, and united with *Mouriria* and *Petalonia* to form a new but doubtful order called *Menecyleæ*.

MENISPERMUM (Linnæus). A genus of climbing plants, chiefly natives of America. They give a title to a natural order, viz. —

MENISPERMACEÆ, which contains eight genera and and twenty-nine species, all twiners or climbers with small inconspicuous flowers. Dr. Lindley says "they are extremely dissimilar in habit from the orders placed near them, and occupy their present station entirely on account of certain minute but important characters in their fructification. With the exception of *Schizandra coccinea*, none of them are worth cultivating as ornamental plants." The famous Columba root, so much esteemed for its intense bitterness, is the produce of the *Cocculus palmatus*. The poisonous drug called *Cocculus indicus* in the shops is the seed of a species of *Cocculus*, probably *tuberosus*. Several Brazilian species of *Cocculus* and *Cissampelos*, are said to possess powerful febrifugal properties. The genera comprised in this order are *Cocculus*, *Coscinium*, *Tiliacora*, *Wendlandia*, *Cissampelos*, *Menispermum*, and *Abuta*; these compose the first tribe of the order; the second tribe containing only *Schizandra*.

MENTHA (Linnæus). A genus of useful and highly ornamental herbs, belonging to *Labiata*. The *M. viridis*, common mint, is one of our most useful culinary herbs, and in constant requisition by the cook.

MENURA—Lyre-tail. A very remarkable species of bird, a native of New Holland, found only in that country, and being the only one of the genus and even the family, as well as only a single species. It belongs, in Cuvier's arrangement, to the dentirostral family of the great order *Passeres*, with which it agrees in the bill being notched, and also in the general form of the legs and feet. But in its air and gait there are some resemblances to the poultry family, though those resemblances are rather slight. They consist in the prevailing tint of the plumage, the short and rounded wings, and the produced feathers in the tail of the male bird. Very little analogy, however, can be founded upon either of those resemblances, and therefore the bird, as we have said, stands alone.

The characters are: The bill broader than high at the base, and triangular in the section there, like the bills of the thrushes. For the greater part of its length the bill is straight, but the point of the upper

mandible is hooked, and furnished with a notch on each side. There is a distinct ridge along the culmen of the bill; and the nostrils are placed in the middle of the bill, in prolonged grooves, very large, oval, and partially covered with membrane, which is beset with feathers as in the bills of the jays. The feet are slender, and the tarsus twice as long as the middle toe. The three front toes are of equal length, the internal one free, but the external joined to the middle as far as the first articulation. The claws are nearly as long as the toes, convex on the upper sides, and blunt. The wings are heavy, rounded and concave, the first five quills increasing regularly in length from the first; and the four next them being equal in length, and the longest in the wing. The tail has very long feathers, and in the male those feathers have a peculiar form, which we shall notice afterwards.

In some respects this is the most beautiful bird of New Holland; and in that country, as well as everywhere else, it stands alone, without there being any genus with which it has any considerable affinity. The colonists, according to the habit which most colonists have of calling new birds of the colony after old birds of the mother country, have given this bird the name of the wood pheasant, and sometimes of the lyre pheasant, on account of the peculiar form of the tail. These terms are misapplications, however, and ought to be discarded; and our knowledge of the bird must rest wholly on the description of itself, without any assistance from analogy.

When the weight, concavity, and roundness of its wings are considered, we need hardly mention that this is a bird which can neither feed upon the wing, nor make long flights, though its wings are, like those of the *Gallinula*, remarkably well adapted for rapid ascents and descents. Accordingly, it is like these in their native localities, a bird of the woods, and passes much of its time in trees or bushes, though it is also found upon the ground, and feeds principally there. Its feeding time is early in the morning, and the male struts about with something of the air of a dunghill cock, though we believe he is monogamous, and no battles of gallantry occur. It is found chiefly in places rather upland, where the ground is dry and covered with trees or brushwood; and its short round wings adapt it well for moving about in such places.

As we said, there is only a single species, *Menura lyrata*, which is about the size of a pheasant, though not so elegantly formed. It is generally speaking of a greyish brown colour, with the throat, and the upper coverts and quills of the wings, reddish brown. None of the colours are bright, neither do they form any very striking contrasts; but, notwithstanding, their general appearance is very striking. It is the tail of the male bird, however, which forms at once the most striking external character, and the greatest beauty of the bird. The tail consists of sixteen feathers, twelve of which, six on each side, have the shafts exceedingly slender, and very few fibres instead of webs; but these fibres are long. The two feathers in the middle have their external webs closely set and straight; and the inner webs almost entirely wanting. The two external feathers are bent like the branches of a lyre; and when the tail of the animal stands erect, it bears a slight resemblance to that instrument, these feathers resembling the frame of a lyre, while the twelve slender ones resemble the strings. It is from this form of the tail that the bird has received its name, which is

not inexpressive of the appearance of this appendage. *Lyres*, for that would be the best English name for them, and it is also the French one, are peaceable and harmless birds, remaining quiet in the shade of the thick branches and leaves during the day, so that they are but seldom seen at that time; and nothing is known with certainty of their nests, the numbers of their broods, or even their time of breeding. The male and female are usually found together, or at least not far apart, when they come out in the mornings and evenings to feed on the ground; and they are apparently very much attached to each other. They are not often seen, except by those settlers who reside very close on the forests in remote parts of the colony; for though their habit appears to be that of feeding upon the ground only, yet they do not frequent grounds on which there are no trees, the shade of these appearing to be indispensable to them in the heat of the day, as well as during the night. The structure of the bill is decidedly insectivorous, or at all events adapted for collecting worms, mollusca, and other small ground animals; and the claws are adapted for scraping, though not so decidedly as those of poultry. In fact the birds, and the country which they inhabit, are both so different from anything else that we meet with, that they would require to be both carefully examined, in order that any just conclusion might be arrived at respecting the adaptation of each to the other, or the use of the birds in the general economy of nature.

MENYANTHES (Linnaeus). An aquatic genus, found in America and in Britain, where it is called *duck-bean*. The genus belongs to the natural order *Gallinacea*. The different species require to be grown in little pools or cisterns, and are propagated by dividing the roots.

MENZIESIA (Smith). A genus of North American and British undershrubs, belonging to the *Ericaceae*. These were associated with the heaths by Linnaeus and others, until separated by Sir J. E. Smith.

MERCURY. This extraordinary metal differs materially from the great bulk of mineral bodies in being occasionally found flowing in a metallic state through the earth. The greater part of the mercury of commerce is, however, procured by distilling native cinnabar, when the metal rises in vapour and is afterwards condensed like steam. Mercury has a very great specific gravity, being heavier than all other fluids. It may be congealed when artificial freezing mixtures are resorted to, and it may then be fractured. The name *quicksilver* is given to this mineral, on account of its fluid form and silvery aspect.

MERGUS (*Mergus*). A genus of web-footed birds, to which the name of *goosander* is given, at least in some of the species. These names are by no means applicable, because the birds have neither the appearance nor the habits of geese of any description. Their characters are: the bill rather longer than the middle size, and much more slender and hard in its texture than the bills of ducks, not being a dabbling or sentient bill like theirs, but a prehensile bill of a very peculiar form. The mandibles are straight for the greater part of their length, but the upper one is much hooked at the point and very sharp, and the cutting edges of both mandibles are in all their length beset with short but strong and sharp teeth inclining backwards. The bill is thus fitted for taking an exceedingly firm hold of slippery prey, and the birds use it in capturing fish. The

nostrils are placed about the middle of the length of the bill, of an oval form and open. The legs are short; placed far backwards as in the divers, and in consequence of this, these birds are much more awkward walkers than the ducks. The wings are of moderate length, but they are clean and firmly made, and the plumage of the body is also close and compact, so that the power of flight is considerable, and when necessary it can be extended to long distances with comparatively little fatigue. As is the case with the ducks, there is an enlargement of the pulmonic end of the trachea, which no doubt answers the purpose of a magazine of air, and enables the birds to remain much longer under water than they could do if not provided with such an apparatus. As the bill of this genus of birds is not adapted for dabbling in quest of soft prey in the mud like the bills of the ducks, or for dividing vegetable matter like those of the geese and swans, it has to find its food by ranging through the waters, and, generally speaking, by diving. In this operation it is by no means so expert as the divers properly so called, and therefore the bird is provided with a more effective apparatus for securing its prey in the hook of the upper mandible and the teeth with which both mandibles are furnished. The principal food of these birds is fish, in the capture of which they are by no means inexpert, so that when they make their inland excursions in temperate climates during the winter, they levy more severe contributions on fish-ponds than any birds which resort to such places, not excepting even the herons, which, though expert fishers and ravenous feeders, by not being either swimmers or divers, are necessarily confined to those portions of the water into which they can wade. In addition to fish, the birds of this genus live upon aquatic reptiles, such as frogs and water newts. They are, in short, abundant rather than particular in their feeding, and hence their flesh is rank and unsavoury, and rarely used as food even by those northern tribes whose supply is the most scanty.

All the genus, at least with some doubtful exceptions, are birds of the high latitudes of the north—that is, they summer, and nestle and rear their broods there. They may also inhabit the high latitudes of the southern hemisphere; but we are very much in the dark as to the economy of living nature in those latitudes, so that we are unable to ascertain with anything like precision, in what respects they agree with or differ from the same latitudes of the northern hemisphere. What lands, or whether any lands of considerable extent may be within the southern polar circle, is not discovered, and apparently not easily discoverable. But if there are few or no lands clear of ice in the southern summer, that is, in our winter, it is perfectly clear that very few birds at all similar to those which visit us from the extreme north in winter, can resort to the regions of the South Pole to breed. Of the birds which have been observed there, to as high latitudes as there are resting places for birds, the greater number, if not the whole, are either long-winged birds which are discursive over the wide ocean, or birds almost wingless, which never move far from the same locality at any season of the year.

There are some other circumstances in the physical geography of the southern hemisphere, which render it necessary that we should not apply to that hemisphere the knowledge which we possess of the aquatic birds which are migrant in the north. In that hemisphere the sea is open fairly round throughout the

whole year for a considerable extent of latitude; and the atmospheric current which results from this, cuts off the polar portion from the portion nearer the tropics, and thus there is not the same interchange of climate and alternation of annuals in the opposite seasons in that hemisphere as there is in the north. In consequence of this the birds which are met with in the most southerly parts of the extensive lands, whether New Holland, Africa, or America, are resident birds, totally different from ours even in corresponding latitudes; and no winter visitants similar to our winter visitants arrive there. So tropical indeed is the ornithology of these countries, that the humming birds are found up to the very extreme point of South America, and they are accompanied by a vegetation which is also tropical.

The seasonal migrations of the aquatic birds of high latitudes is one of the most interesting parts of their history, because they are evidences of the geography of different localities, and very correct tell-tales of the weather in the regions from which they come; and it is of importance to know that the general knowledge which they afford us with regard to the north, does not at all apply to the corresponding latitudes of the south.

The genus *Mergus* are all migrant, though they are not all equally polar in their summer residence and economy. One species, at least, lingers in a straggling remnant upon some of the remote isles north-westward of Scotland, and also in the extreme north-west of the main land. It is true, that this is but a remnant; and, unless the winter in the high latitude is exceedingly severe, the birds are not, generally speaking, numerous even in the northern parts of Britain, and they are comparatively rare in the southern. In the western part of the continent they are, perhaps, more abundant, and certainly extend more to the south than any part of Britain; but the continental winter is, latitude for latitude, colder than ours; and the birds which take the range of the North Sea, necessarily pass to the Netherlands or the North of France before they find a resting place. It is the same with all the birds which come from the regions of the poles in winter, the whole of them get more southerly in France than they do in England. We have already mentioned that these birds feed chiefly upon fish and aquatic reptiles; and their bills are not adapted for taking, or their stomachs for digesting, vegetable matter of any kind, and none of them are known to feed upon the land, for which they are equally ill adapted by the structure of their bills, and their short and backward feet. The latter are so ungainly, that they could pick up hardly any land substance, not even an insect or a worm; and their pace is so slow and wriggling that they could follow nothing which possessed any degree of land motion. They are, therefore, entirely cast upon the waters for their subsistence, and when frozen out in one place, they have no alternative but to take their departure for another.

The species of these birds were for a long time very much confused by describers, and multiplied to at least double the number that really exist; and it was reported by some naturalists that a species was met with in tropical latitudes on the coast of Brazil, but this is very unlikely, and contrary to the analogy of the birds, which, when they migrate from their polar localities, seek the inland lakes and rivers, or at all events the estuaries rather than the open sea. The cause of the multiplication of species beyond the real

number, was the same as that which had introduced confusion into many other parts of ornithology; the females are differently coloured from the males, and the young are different from the mature birds of both, so that in any one of the species, those who founded their distinctions upon colour alone could easily divide it into three. There are at least four well-authenticated species, one of which certainly breeds in some parts of the British islands, another probably does so though more rarely, and the other two are rare even as stragglers. The English names given to the different species vary; the largest being called Goosander, two of the others Merganser, and the remaining one the Smew, or white nun.

The *Goosander* (*M. Merganser*). This is the largest species of the genus, the male being about four pounds in weight, twenty inches long, and upwards of three feet in the expanse of the wings. Its summer residence is in the northern parts of both continents, and it is probable that a few, though a very few, may linger during the summer about the extreme north of Scotland. In winter it is very discursive, and more so in proportion as the winter sets in more early and severe. It visits many parts of the British coast, according as these lie more in the line of its progress southward; and on the continent it finds its way to the lakes and ponds of Germany and even of Switzerland. As it inhabits round the entire circumference it is equally migrant in Asia and America as in Europe; and as Finland is a country abounding in pools and streams, many stop to breed there.

Goosander.

The bill is ample in the gape, but rather shorter than in some of the other species. In the greater part of its length it is slightly bent upwards, but the tip of the upper mandible is strongly hooked downwards, and consists of a nail of harder texture than the rest of the bill. The cutting edges are very strongly toothed, so much so that the bird is popularly known by the appellation of "Jack-saw." The general colour of the bill is red; but a portion round the nostrils, the ridge of the upper mandible, and the nail on its tip are dusky. The inside of the gape is bright orange. The head and crest, the last of which is most conspicuous in the male, together with the upper part of the neck, are dark green, passing into black on the chin and throat. The lower part of the neck, the outer scapulars, the breast, and all the under part of the body, are white with a tinge of yellowish red. The back, and scapulars next the back, are black, fading into greyish toward the rump, and the

tail, which consists of eighteen pointed feathers, is of a grey colour. The principal quills and coverts are brownish black, with the exception of the middle secondaries and the extremities of their coverts, and these form a white speculum or wing-spot. The head and neck of the female are rust-coloured, the upper part is of a greyish tint, and the under part white with a yellowish shade. In consequence of this she has been figured and described as the "Dun Diver;" and the young male, which resembles her in colour, has been considered as the male of the same. The bill and feet are reddish ash colour.

This species is strong and active, and a most successful fisher, so that when it comes southward its visits to fish ponds are by no means courted. The nest is generally formed among rocks and stones, though sometimes in the holes of trees; the eggs are rather numerous, being a dozen or more; they are of a yellowish white colour, and taper almost equally to both ends. In some countries they are eagerly sought after as articles of food, though the flesh is hardly eatable by anybody. The male attends the female during the incubation; but as soon as the young appear the sexes separate, and the males associate in one place, while the female and her brood remain in another, till the end of the summer, and probably till the pairing time again comes round. In all probability this is the reason why the male was described as one species under the name of goosander, and the female and young male as another species, under the name of the dun diver. This is a point in the economy of birds to which it is necessary to attend, especially where the females and young resemble each other in colour, and are different from the males.

Red-breasted Merganser (M. serrator). This is a smaller species than the former, measuring only about one foot nine inches in length, and two feet and a half in the stretch of the wings, and its weight does not exceed two pounds. It is, however, a bird of more powerful wing than the goosander, and therefore it is more discursive. It breeds far to the north, as far as Hudson's Bay; but as it also ranges far to the south in the winter, stragglers remain to breed in southerly places. In severe winters it is not uncommon on some parts of the northern shores of the Mediterranean, and it is particularly abundant in the lagoons about Venice. It quits all these southerly latitudes when the spring begins to break; and about the beginning of June it reaches its most northerly latitudes, where it immediately begins the grand business of the season. The nest is usually in concealment, close by the margin of some fresh water. Externally the nest is formed of dry stalks and withered grass, and the bird pulls the down from its own breast to form a soft lining for the interior. The eggs are about the size of those of a common duck, of an ash-coloured white, and averaging about a dozen in number.

The bill is long for the size of the bird, measuring full three inches from the gape to the point; the edges are toothed in their whole length, more closely than the goosander, but they are not so distinct, neither is the point of the upper mandible quite so much hooked. The feet and middle part of the breast red with some dusky mottlings on the latter. The hind part of the head has a loose crest, pendant over the eye, and that and the head and the upper part of the neck are deep green, with reflections of purple.

The upper part of the back is black, the lower part and the sides of the flanks mottled with brown and grey. A spot on the shoulder, the scapular feathers next the wing, the wing-spot and the belly, white; but the wing-spot is surrounded by black, and crossed by two lines of the same colour. The head and neck of the female are brownish, the breast mottled with grey, the back ashen grey, the wings dull brown, with only one black bar across the wing-spot.

The *Smeu*, or *White Nun (M. Albellus)*, is, like the rest, a native of northern climates, and very abundant in both continents. It is smaller than either of the former two, more elegant in its form, more decided in the markings of its plumage, more vigorous on the wing, and more discursive. It is in fact one of the most elegant of the aquatic birds, and one which is very lively in its motions, whether in the air or in the water.

The male bird measures about a foot and a half in length, and two feet three inches in the expanse of the wings; and its weight is a pound and a half or a little more. The bill is about two inches in length, tapering toward the extremity, which has a strong hooked nail, but the edges are not so deeply toothed. The prevailing colours are pure black and white, finely contrasted with each other, only some portions of the black have beautiful green reflections in some positions of the light. This is the case with a large and well-defined spot on each eye; and the under part of the crest is black, which marks very perfectly the contour of the hind head, and makes the upper or white part of the crest appear like a detached streamer. The rest of the head, the neck down to the shoulders, and all the lower part, are spotless white, except the under sides of the wings, which are beautifully waved with black lines. The middle of the back is black, but the scapular feathers are white, except a few elegantly curved of black, which extend toward the breast, and the anterior of the three pairs of curves almost meet in front. The edge of the wing, the primary quills, and the greater coverts and secondaries, are black, only the last two have white tips, which form a broad patch and two narrow bands of that colour. The tail, which consists of sixteen feathers, is dark ash colour. The female is not nearly so large as the male; the crest is also smaller and reddish brown, the spot on the eye is dusky; there is a pale brown collar round the neck; the shoulders and breast are pale brown; and those parts which are black in the male are dull ash colour in the female. The bill and feet in the male are bluish black; those in the female are pale blue. The young males are marked in the same manner as the female, and this has of course given rise to the supposition that both were of a different species from the mature male.

These birds range further to the south than perhaps any of the others, both in the eastern continent and in America; and wherever they visit, the elegance of their forms, and the strong contrast of colours in their plumage, render them objects of great attention.

The *Hooded Merganser (M. cucullatus)* is understood to be peculiar to the American continent, unless when it straggles eastward, which, even in Britain, is very rare. It is rather longer than the white nun, but shorter in the wings, and not so handsome a bird. The bill is very much toothed, resembling that of the goosander both in shape and colour. The eyes are small and golden yellow, and the feet reddish. The head is furnished with a large crest which spreads like

a hood, and is black at the base and tip, and white in the middle part. The neck and upper part of the back black, broken by two bars of white extending from the breast. Under part white, passing into reddish brown backwards, and delicately marked with black on the sides and flanks. The primary quills, and the tail feathers, of which there are twenty, are dull black. The smaller coverts are ash, but the greater coverts and secondaries form two white lines and two black ones in the middle of the closed wing. The female is smaller than the male, and tinged with russet colour.

MERIANIA (Swartz). A genus of beautiful West India evergreen shrubs, known by the name of the mountain or Jamaica rose. The flowers are decandrous, and the plants belong to *Melastomaceæ*. They succeed in the stove, and may be increased by cuttings.

MESEMBRYANTHEMUM (Linnaeus). A numerous genus of succulent plants, commonly called the fig-marigold, from the shape of their flowers, which are icosandrous, and their fig-like fruit. They belong to the order *Ficoideæ*, and are chiefly natives of the Cape of Good Hope. So numerous are the species, that they are divided into eight sections, significant of their forms or manner of growth. The dwarf kinds should be kept in small pots in very sandy or gravelly soil, and require but little water at all seasons, but particularly when they are dormant. They only require to be defended from frost in a green-house or frame, and are easily propagated by cuttings kept dry till they produce roots.

MESPILUS (Linnaeus). Is the generic name of the common medlar, of which there are three sorts cultivated for their fruit, and one species, the *M. grandiflora*, is ornamental. The flowers are icosandrous, and belong to *Rosaceæ*. See **MENLAB**.

MESSERSCHMIDIA (Linnaeus). A genus of trees and climbing shrubs, natives of the West Indies, formerly called *Tournefortia*. They belong to *Boraginææ*. They are stove plants; but as their flowers are by no means showy, they are only met with in general collections.

METROSIDEROS (Gærtner). A fine ornamental genus of trees and shrubs, chiefly found in New Holland. They belong to *Myrtaceæ*. One of the species, *M. verus*, is the true iron-wood of India, and so hardy and heavy as to be fit for the construction of ships' anchors. This tree is kept in our stoves, and grows well with ordinary treatment. The New Holland species are green-house plants, and all require a mixture of loam and moor-earth; and propagation by cuttings of the ripened wood.

MEXICAN LILY. Is the *Amaryllis reginae* of Linnaeus. One of the most splendid of the tribe.

MEXICAN TIGER FLOWER. Is the *Tigridia pavonia* of Jacquin; an estimable though a very fugitive gem of the flower garden, but remarkable both in form and colour.

MEZEREUM. Is the *Daphne Mezereum* of Linnaeus, one of our most common ornamental shrubs.

MICHAELMAS DAISY. Is the *Aster Tridactylus* of Linnaeus, a common inhabitant of our flower borders.

MICHELIA (Linnaeus). A genus of lofty trees and straggling shrubs, natives of India and China, belonging to *Magnoliaceæ*. The flowers are yellow and beautiful, and the trees may be propagated by cuttings or by grafting on the purple Chinese Magnolia.

MICONIA (Ruiz and Pavon). A genus of evergreen tropical shrubs, separated from the genus *Melastoma*, though closely allied thereto. The foliage is good, the flowers white, lilac, or rose-coloured. They affect a soil of loam and moor-earth, and may be propagated by cuttings.

MICROGASTER (Latreille). A genus of minute parasitic hymenopterous insects, belonging to the family *Ichneumonidae* and sub-family *Braconidae*, having the second submarginal cell minute, the abdomen and ovipositor are small, the lower parts of the mouth are not elongated, and there is not any remarkable space between the jaws when closed. These little insects are amongst the most destructive enemies of various smooth lepidopterous larvæ, amongst which the caterpillar of the common white butterfly of the cabbage (*Pontia brassicæ*) affords the most common example, and which is often observed, after it has ceased feeding and taken its station upon some outside window-frame, paling, &c., to produce a great number of minute oblong balls of silk of a pale yellow colour, instead of undergoing the ordinary transformation to a chrysalis. These little balls are the cocoons of a small species belonging to the present genus, of a black colour with yellow legs (*M. glomeratus*), the eggs of which had been previously deposited by the parent fly, in the larva upon the body of which it takes its station, repeatedly plunging its ovipositor between the rings and lodging an egg at each thrust, the larva appearing all the while to take but little heed of the proceedings of its enemy. The little parasites as soon as hatched feed gregariously upon the fatty substance of the larva, bursting out simultaneously when full grown, and immediately encasing themselves in the yellow cocoons above mentioned, and which, as observed by Mr. Haliday, the indefatigable historian of these minute tribes, "are composed of a very fine glossy silk of one colour, which can be wound off like that of the silkworm, whilst in most of the remaining *Ichneumones* they are of a gummy texture and banded. They are arranged in various modes, examples of which, and a minute account of the process of construction, may be found in the second volume of Reaumur's Memoirs. The larvæ are generally supplied with a twofold secretion of silk, that which comes out first being of a looser and coarser texture, and serving for a common envelope for the whole society. The sections into which the genus has been divided do not appear to be characterised by a particular disposition of the cocoons, as this differs in species the most nearly related; some are collected into a ball, and entirely concealed within a thick cottony mass attached to a stalk of grass (as *M. globatus*, *imbricatus*, &c.); others are fastened round a twig, and arranged side by side like the cells of a honeycomb (*M. alvearius*, *alvearifer*). In many they are scattered or collected in an irregular heap, and covered with a loose web of open texture, but tough, as is the case with *M. glomeratus*, the most familiar species which keeps down the numbers of the common white butterfly. A correspondent in London's Magazine, vol. iii. p. 52, affirms that the caterpillar of the butterfly spins the outer web over its parasites, and Gødart has written the same; Madame Merian has a similar statement relative to the caterpillar of the *Cynthia Cardui*, and its microgaster. I am more inclined, however, to place my faith in the usual accuracy of Reaumur. It would be a singular fact that the caterpillar of a butterfly, which for its

own transformation produces only a few threads which fasten the tail and girt the middle of the chrysalis, should become provided with the superabundant supply in consequence of its interior being nearly devoured. In the case of those species indeed which infest the tribes of *Bombyces* and *Arctice*, it appears that the imperfect cocoon spun by the caterpillar may serve for the envelope of its parasites. In general they are found in lepidopterous larvæ, but Mr. Curtis has obtained one species out of that of an aphidivorous fly."

In the eighth number of the Entomological Magazine, Mr. Haliday has given a monograph of the genus, describing fifty species, and indicating more than twenty others described by previous authors. They are all of minute size, not exceeding one eighth of an inch in length.

MIDGE. The ordinary English name given to numerous minute species of *Tipulidæ*, having the appearance and being of the size of the common gnat, but wanting the elongated proboscis of that insect. They chiefly belong to the genera *Chironomus*, *Corethra*, and *Tanyptus*, and are often miscalled gnats, which name ought to be restricted to the family *Culicidæ*.

MIGNONETTE. Is the *Rexeda odorata* of Linnaeus, a well-known flower-garden plant.

MILFOIL. Is the *Achillea anglica* of G. Don, a common plant in every pasture, belonging to *Compositæ*.

MILIOLA (Lamarck). A minute shell which has been found on Fuci in the island of Corsica; it is also frequently met with in a fossil state. It belongs to the family *Spherulaceæ*.

MILIUM (Linnaeus). A genus of grass, chiefly annuals, found in different parts of Europe. The *M. effusum* is the millet-grass of English botany.

MILKWORT. Is the *Polygala vulgaris* of Tournefort, a common plant found in dry pastures.

MILLERIA (Linnaeus). A genus of tropical annuals, named in honour of "the prince of gardeners," Philip Miller, F.R.S., many years curator of the Chelsea botanic garden. In our collections they are treated as tender annuals; i.e. sown in a hot-bed or hot-house, and planted out in the borders before Midsummer, where they ripen seeds. They belong to the order *Compositæ*.

MIMETES (Dr. R. Brown). A genus of evergreen shrubs from the Cape of Good Hope, belonging to the *Proteaceæ*, and nearly allied to the type of that order. These plants do not thrive well with much moisture, and therefore require to be grown in well-drained pots and in light sandy loam. They may be propagated by cuttings if kept free from damp.

MIMOSA (Linnaeus). A genus of plants so called, because some of them imitate the action of animals by shrinking from the touch of other bodies. The *Mimosa* are distinguished from *Acacia* by their jointed pods and sensitive properties. They grow well in the green-house mixture of loam and moor-earth, and may be propagated by cuttings, but much more conveniently by seeds. They belong to the natural order *Leguminosæ*.

MIMULUS (Linnaeus). A genus of very interesting annual and perennial herbs, natives of America. The flowers are didynamous, and the genus belongs to the natural order *Scrophularinæ*. They grow in any rich soil, and are readily increased from seeds which ripen abundantly. There are many new varieties of the British species.

MINERALOGY. Our earth has sometimes been defined as a "huge mineral," but the discoveries in modern chemistry show that it is composed of a vast number of compound bodies continually acted upon by changes of temperature, and the solvent character of the fluids which percolate through the interstices which it contains. The characters of these bodies differ most materially both in their external appearance and in their effects on the human frame. Thus we find in the same neighbourhood poisons of the most deadly character assuming forms of the most exquisite symmetry, whilst metals which are of the greatest service in domestic economy and the useful arts are apparently worthless if not repulsive in their appearance.

The iron that forms the warrior's weapon as well as the more useful implements of the agriculturist, can only be procured with advantage by an acquaintance with the mineral bodies with which our earth is so thickly studded; and the steam engine, that mighty abridger of time and space, owes much of its utility to this country having given a peculiar degree of attention to practical mineralogy. The great importance of the mineral kingdom in a scientific point of view is in no shape confined to the natural history characteristics of mineral bodies; and though the properties which some minerals possess of phosphorescence, electricity, and magnetism, may only serve to excite the attention of the curious, yet the ablest mathematician may find ample employment in the more abstruse problems of crystallisation and polarised light. This is, at the same time, the science which includes within its ample range the marbles of the statuary and the architect, the metals of the manufacturer, the gems of the jeweller, and the soils of the agriculturist. It can never, therefore, be deemed uninteresting or unimportant. Nothing can be more beautiful than the caverns to be met with in primitive rocks, whose walls are lined with pure and various coloured crystallised topaz, beryl, and rock crystal; and the gneiss, granite, and mica slate, with imbedded grains and crystals of sapphire, chrysoberyl, garnet, emerald, and ruby, seem to realise the oriental tales of diamond valleys and emerald caves. But it is not the beauties of the gems alone that attract our attention; the varying composition of the mighty masses which compose the crust of the earth's surface, and their conversion into soils no less than the operations at once mighty and minute which turn the hard and sterile rock into soft and fertile earth, are well worthy of our attention. Some idea may be formed of the method in which this is performed by referring to the instance of porcelain granite. "This substance," says Sir Humphry Davy, "consists of three ingredients—quartz, feldspar, and mica. The quartz is almost pure siliceous earth, in a crystalline form. The feldspar and mica are compounded substances; both contain silica, alumina, and oxide of iron; in the feldspar there are usually lime and potassa; in the mica, lime and magnesia. When a granite rock of this kind has been long exposed to the influence of air and water, the lime and the potassa contained in its constituent parts are acted upon by water as carbonic acid, and the oxide of iron, which is almost always in its least oxidised state, tends to combine with more oxygen; the consequence is that the feldspar decomposes, and likewise the mica, but the first the most rapidly. The feldspar, which is as it were the cement of the stone, forms a fine clay; the mica,

partially decomposed, mixes with it as sand, and the undecomposed quartz appears as gravel or sand, of different degrees of fineness. As soon as the smallest layer of earth is formed on the surface of a rock, the seeds of lichens, mosses, and other imperfect vegetable bodies which are constantly floating in the atmosphere, and which have made it their resting place, begin to vegetate; their death, decomposition, and decay, afford a certain quantity of organisable matter, which mixes with the earthy materials of the rock; in this improved soil, more perfect plants are capable of subsistence. These, in their turn, absorb nourishment from water and the atmosphere, and, after perishing, afford new materials to those already provided; the decomposition of the rock still continues, and at length, by such slow and gradual processes, a soil is formed in which even forest-trees can fix their roots, and which is fitted to reward the labours of the cultivator."

We cannot better illustrate the general character of our mineral treasures than by briefly referring to that universally diffused one—iron. The immense supplies for the arts of life are usually drawn from the oxides. It is so abundant that there are few fossils free from it, and many mineral waters contain it. When we examine any chasm in the earth's surface, it will generally be found tinged with a reddish hue, and the intensity of the colour will generally furnish some indication of the amount of ferruginous matter that it contains. But a better and equally simple test may be found in the use of a little of the infusion obtained from bruised galls in water, which on being blended with the suspected body will become of a dark colour. This mode of ascertaining the presence of iron is exceedingly valuable as, on account of the universality of this mineral, there are many sites entirely valueless as domestic residences from the quantity of iron with which the water is impregnated. But we are not to suppose from this that pure or native iron can be raised from the earth in every region, as the cases in which it really occurs are very rare. Where it is so found there can be little doubt that it is generally of meteoric origin. Such for example is the mass weighing about 1600 pounds found by Professor Pallas in Siberia, and a mass weighing fifteen tons discovered by Rubin de Celis in Peru.

There are several varieties of mineralised iron which generally consist of the metal combined with oxygen. Indeed the native oxides constitute a very extensive and important class of metallic ores. They vary in colour, depending upon mere texture in some cases; in others, upon the degree of oxidation. Some varieties are magnetic, and those which contain least oxygen have the greatest magnetic power. The hematite, or red iron-stone, is of a very peculiar character. It occurs in globular and stalactitic masses, and it may be proper to observe that most of our iron plate and wire is made from it. But clay-iron-stone is the mineral which produces the greatest quantities of cast and bar iron. This in a great measure arises from the proximity of coals with which it is usually accompanied.

When we look at either of these minerals, it must be sufficiently obvious that they bear but little resemblance to the bright and shining body to which they are afterwards reduced. The essential part of the process by which this is effected consists in decomposing them by the action of charcoal or coke at high temper-

atures. Thus the argillaceous iron of Wales, Shropshire, &c., is first roasted, and then smelted with limestone and coke; the use of the former being to form a fusible compound with the clay of the mineral by which the latter is enabled to act upon the oxide, and to reduce it to the metallic state.

Our space will not admit anything like a detailed history of the science of mineralogy, or of the various systems of classification that have been pursued; and, for a view of the mineral bodies themselves, we must refer the reader to their alphabetical order in the present work. It may, however, be proper to state that as a science it is little more than half a century old. Previous to that time fine collections of minerals existed, but more advantage may now be derived from studying the beautifully arranged cases of specimens in the British Museum for a single morning, than could have been derived from a lifetime according to the old and inaccurate mode of classification. In the beginning of the last century the descriptive language of mineralogy was vague and ambiguous, each author using that which seemed to him best to answer his present purpose. Now, however, a slight acquaintance with chemistry and the mathematical sciences enables the mineralogist to as accurately discriminate his specimens, and communicate his knowledge to others, as in the classification of a library.

The celebrated Berzelius has attempted to establish a pure scientific system of mineralogy, by the application of the electro-chemical theory and the doctrine of chemical proportions. The views which he disclosed are novel and highly important. He defines mineralogy to be the science which treats of the elementary combinations of inorganic substances found in or upon the earth, and of the various forms and different foreign admixtures under which these bodies make their appearance. The object of Berzelius is to show that the influence of the electro-chemical theory extends as much to mineralogy as to chemistry; and also that the doctrine of definite chemical proportions is equally applicable, and will give the same degree of mathematical certainty to the arrangements of a mineralogical system which it has already given to chemistry. "From the electro-chemical theory we have," says he, "been taught to seek in every compound body for ingredients of opposite electro-chemical properties, and we have learned from it that the combinations cohere with a force which is in proportion to the degree of opposition in the electro-chemical nature of the ingredients. Hence it follows, that in every compound body there are one or more electro-positive, and one or more electro-negative ingredients. By electro-positive ingredients he designates such as have inflammable bodies, or salts for bases; and, by electro-negative, the oxygen and oxides which go to the negative pole of the voltaic battery. In other words every substance called a basis, in chemical combination, must have another which acts the part of an acid, though the latter, when uncombined, may not be distinguished by an acid flavour, or the property of changing vegetable blues to red. The body which, in one case is electro-negative, may, in another case, be electro-positive, and may be united to a stronger electro-negative, that is, it may be the basis to a stronger acid.

Berzelius divides simple bodies into three classes: *Oxygen—simple combustibles not metallic; or metalloids; and metals.* A general notion of their arrangement

may be derived from the following brief tabular view :—

1. <i>Oxygen.</i>	Sodium,
2. <i>Metalloids.</i>	Potassium,
Sulphur,	Molybdena,
Nitric,	Tungsten,
Muriatic Radical,	Antimony,
Boron,	Tellurium,
Carbon,	Silicium,
Hydrogen.	Columbium,
3. <i>Metals.</i>	Titanium,
Arsenic,	Zirconium,
Chrome,	Osmium,
Uranium,	Bismuth,
Zinc,	Iridium,
Iron,	Platinum,
Manganese,	Gold,
Cerium,	Rhodium,
Yttrium,	Palladium,
Glaucinium,	Mercury,
Aluminum,	Silver,
Magnesium,	Lead,
Calcium,	Tin,
Strontium,	Nickel,
Barium,	Copper.

Each of these bodies may constitute a mineralogical family, composed of the simple body, and all its combinations with other bodies which are electro-negative with respect to it; that is, with those which, except in a few cases, stand above it in the preceding table. The families are divided into orders, according to the different electro-negative bodies with which the electro-positive is combined.

MINNOW (*Leuciscus phoxinus*). A genus of soft-finned fishes with abdominal fins, belonging to the carp family, or the first into which Cuvier divides the soft-finned orders. The minnow is of small size, rarely exceeding three inches in length, and seldom measuring as much. It is in fact the smallest of the family, and we believe there is only one known species of the genus. Minnows are exceedingly abundant in all the clear running brooks and streams of every part of England, and of the temperate parts of the continent. They do not occur in the larger rivers, except in little eddies of shallow water, where they can pass their time undisturbed by the violence of the current. They are exceedingly fertile, and though they form no inconsiderable portion of the food of every larger fish which inhabits or visits the same waters, they still remain the most abundant of the whole; and in the fine clear trouting streams, however abundant trout may be, there are probably ten thousand minnows in the shallows near the banks for every trout which is in the pools or stronger currents. When the water becomes swollen by a heavy fall of rain, the minnows are, so to express it, broken loose from their moorings, and vast numbers of them are at the mercy of the stream, against which their light weight and small strength are but ill able to contend. It is then that trout and pike and other fishes, which can head the water with more security and power, are on the alert and fare sumptuously on the agitated and defenceless minnows. The angler takes advantage of this, and either places a minnow on his hook, so bent as that its body may wriggle as it is drawn along, and show the bright lustre of the scales in various points of view, or he has an artificial form of a minnow prepared, of the same form as the real one, and used in the same manner. The real minnow is

by far the better bait for trout, and also for large perch, and for salmon; and if the water is of the proper height and colour, and the angler understands it, and can handle his tackle well, finer fish may be obtained by this than by any other method of rod and line fishing. They can also be landed with greater certainty and in less time, inasmuch as a stronger line may be used than in fly-fishing, or in fishing with the smaller species of bait. The artificial minnow is better adapted for fishing for pike, inasmuch as the pike are more voracious than the fishes which have been mentioned, and more readily bite at any substance which is moving in the water, without any great nicety as to what may be its nature.

The minnows themselves are voracious enough in their little way; and, though they are incapable of swallowing a live fish of any considerable size, they nibble away at a dead one. They are by no means alarmed or even disturbed at the presence of man; and in the clear little pools of the streams of pure water, the boys sometimes amuse themselves with what they call making "minnin tulips." [It is to be understood that the words minnow and minnin have exactly the same meaning, and appear to have been derived from the Latin *minimus*, the smallest.] The tulip is made in this way—a crumb of bread or piece of worm is dropped into the water, usually tied to a small pebble with a bit of thread, in order that it may sink the more rapidly and be the less easily removed. The minnows, which are sporting about through the water, crowd to the descending substance from all sides, and when it reaches the bottom there are generally as many heads in contact with it as can be wedged round, the axis of the fishes being inclined upwards toward the tails, and thus the whole bearing some resemblance to the petals of a flower, though certainly not much to those of a tulip. A small metal button which is bright and shining will produce a similar assemblage, but a tulip collected by such an object is a very fading flower.

The capture of minnows is an equally easy matter. A crooked pin at the end of a bit of thread fastened to a small twig, and baited with a little bit of earthworm, furnishes ample tackle for the youthful angler; and when there is little stirring in the waters, the pin itself will sometimes do without any bait. There are few places in which minnows are taken for any other purpose than as bait for other fishes, or as a first attempt in angling to the boys; but where they can be taken in sufficient quantity by means of a small meshed casting net, which can be readily done in some places, they are said to be very delicious, though the dressing of a single minnow, or even a dozen or two, would be a most unprofitable waste of the culinary art. In the matter of fishes as an article of food, our judgment is in some danger of being carried away by mere size; and yet of fishes of the same genus or the same family the small species, when of equal age and in equal condition, are invariably more finely flavoured than the large ones.

The minnow, being a delicate little fish, spawns in the warm season; the operation is soon over, and the young are alive in the course of not more than a week from the time of their being deposited in the fine gravel, in shallow water, and freely exposed to the sun, which is their usual nidus. It is said that the female minnows are diandrous, or always attended by two males when depositing the spawn; and it is probable that other fresh water fishes have the same

habit. When the young minnows first come out of the egg they are exceedingly minute, and so transparent that hardly any part of them is visible, except the eyes, which are large and dark coloured. The little things require indeed to have their eyes about them, because they are exposed to many enemies. The more advanced fry of those fishes which spawn early live upon them in a great measure; and so do the larvæ of many insects which pass that stage of their existence in the waters.

At all times, indeed, the minnows appear to be destined as the prey of one or another of their fellow inhabitants of the waters; and in this way, small as they are, they are not unimportant in nature's economy. When the trout and salmon ascend the brooks and streams for the purpose of spawning, the minnows serve them in great part as food in situations and at a season when other food for them is but scanty. The young again are ready to supply the young of those fishes; and thus the minnows, endowed themselves with highly prolific powers, are the cause or the means rather, of keeping up those races which are more useful to man. The upper part of the minnow is of a dusky olive colour, a little mottled, and gradually passing into a lighter tint on the sides. This passes into a tint of delicate pink in the summer season; but the pink is the nuptial livery of the fish, and wears off in the winter. The irides and gill-covers are silvery white, and the fins brown; those on the under side of the body paler than the others. The body is long and slender; the head about one-fifth of the length, exclusive of the caudal fin. The tail is large for the size of the fish, and very much forked. The dorsal and anal fins are also pretty large; and altogether this little fish is a clever swimmer. The body is covered with very minute scales, and marked with a distinct lateral line, which is straight in the posterior part of the body, and bent upwards in the anterior part. The minnow, though one of the smallest of our native fishes, is far from being one of the least interesting; and it is so generally distributed, and so little prone to concealment in its habits, that it may be said to be more open to observation than any of the rest.

MINT is the *Mentha viridis* of Linnæus. A common garden herb.

MIRABILIS (Linnæus). A genus of South American tuberous rooted herbs long cultivated as ornamental plants in gardens. They belong to the fifth class of Linnæus, and to the natural order *Nyctagineæ*. The marvel of Peru is universally known, it having a place in every garden. The roots must be taken out of the ground during winter, and kept in a dry place out of reach of frost. In the spring they should be replanted in the open border, to flower in the autumn.

MIRBELIA (Smith). A genus of evergreen shrubs, natives of New Holland. The flowers are decandrous, and belong to the natural order *Leguminosæ*. The best soil for them is a mixture of loam and moor earth, and the cuttings will strike roots in sand under a bell glass.

MISTLETOE is the *Vicium album* of Linnæus. A curious parasite shrub growing on different sorts of trees in English woods. It belongs to the order *Loranthæ*.

MITE. The ordinary English name of various minute apterous insects, forming the Linnæan genus *Acarus*, or the order *Monum. rosomata* of Leach, by

whom, however, these insects have been constituted a distinct class of the articulated animals, in which respect he has met with no followers. The structure of the insects being referrible to the arachnidous type, although the mode of respiration by tracheæ differs from the more typical *Arachnida*; but in this group the characters derived from the respiratory organs have recently been proved by the researches of M. Duges to be of but a secondary importance. Various interesting peculiarities relating to these insects are detailed in the article *ACARUS*; but the chief motive in our again noticing them is to mention the very valuable discoveries lately made by M. Duges, an indefatigable French naturalist, by whom it has been proved that they undergo metamorphoses consisting in some groups of an increase in an additional pair of legs, whereby one of the sections proposed in the group by Latreille and Hermann (*Trombides herapodes*) is found to consist only of insects in an imperfect state, whilst in others the change of form is complete. This is especially the case in the water mites, the larvæ of which have a very large head and six legs; the pupæ are inactive, attaching themselves by a single pair of very short legs to the bodies of other aquatic insects, and being composed as it were of an oval bag with a narrow neck; the insect in this state having been formed by M. V. Audouin into the genus *Achlysia*, and being specifically named *A. dytici*, from taking up its residence beneath the elytra of the great water-beetle *Dytiscus marginalis*; they also attach themselves to the slender filaments composing the tails of the water-scorpions (*Nepa* and *Ranatra*).

MITELLA (Linnæus). A genus of small North American perennial herbs, belonging to *Saxifragææ*. The flowers are white and pretty, and well fitted for rockwork.

MITRA (Lamarck; *Voluta*, Linnæus). This very numerous and truly elegant genus of molluscs was confounded by Linnæus with his genus *Voluta*, from which it so essentially differs in many characteristic distinctions that its separation is obviously necessary. These are that the summit of the spire is always pointed, and never terminated in a papillary form; the plaits on the columella gradually diminish in size towards the base; the upper are consequently larger than the lower; they are always transverse and parallel to each other; the columella lip exists, though sometimes very thin, and only visible at the base, and some species possess an epidermis. The general form of the *Mitra* is turretted or subfusiform, base notched, no canal, no operculum. No shell presents greater beauty of sculpture and colouring than some of this species. They are of every possible pattern, with transverse grooves, punctures, granulations, striæ, and sometimes smooth, the colours of every hue. In some species the upper part of the whorls, being crenulated and the outward lip dentated, are additional characters, distinguishing them from the *Volutes* in which these never occur. Four subdivisions may well be formed of this genus: the first, of such as are turriculated, the aperture very narrow, ribbed, and with one plait, the *M. tenuata*; secondly, those turriculated, the aperture wide, and large spiral whorls, the *M. episcopalis*; thirdly, the sub-oval species, with a short spire, generally tuberculated, the *M. microzonias*; and lastly, those of an oval form and a very short spire, by some authors called the *M. olivaria*, an example of which is the *M. dactylus*. The

animal is not described; they inhabit the seas of hot climates, and several fossil species are known.

MODECCA (Jacquin). A curious genus belonging to *Passifloræ*, discovered at Sierra Leone, and also in India. In the stove it requires a soil composed of loam and moor earth, and may be propagated by cuttings placed in heat under a glass.

MOLE (*Talpa*). A genus of mammalia belonging to the order *Carnassier*, and to the insectivorous division of that order. The common English name mole is derived from "mould," "mowle," or "moole," all of which are varied pronunciations of the Anglo-Saxon name for that portion of the surface substance of the earth which consists in great part of decayed vegetable matter, is more favourable for the roots of growing vegetables than any other kind of earth, and which is on this account more frequented by earth-worms and ground larvæ. In a state of nature the mole is the regulator set over these; and, as it has to perform more severe labours in the procuring of its food than any other known animal, it is both in instinct and in structure better adapted for this purpose. Of all animals the mole is the most ravenous and the most impatient of hunger, so that a very brief suspension of feeding works it into an absolute frenzy; and if two moles are shut up together, for even a very short time, without anything to eat, they speedily engage in desperate combat, and never desist until one is vanquished, and then the conqueror instantly begins to make a meal of the other. Among animals inhabiting the surface of the ground in the ordinary way, this would be reckoned a very cruel disposition; but when we consider the habits of the mole, and the mode in which it must proceed in the finding of its food, we must regard this extreme and ungovernable appetite as the very perfection of its character. Other animals have to pursue their food through the air or the water; and upon examining them it will be found that their instinct for food is strong in proportion to the degree of fatigue which they must undergo in the procuring of it. The mole has to pursue its food through the solid earth, and therefore the analogy requires that its propensity for feeding should be strengthened in proportion to the labour which it must undergo. We shall afterwards have occasion to notice more particularly the structure of their permanent covert-ways, or passages which the mole constructs for itself under the ground; but we may in the mean time mention, as illustrative of the general fact of its adaptation to the place which it occupies in nature, that the mole finds no part of its food in those permanent covert-ways or galleries, but that every time it eats below the surface (and it does this for the greater part of its active life) it must bore through fresh earth, and thus, for a small portion of its meal, it must undergo more fatigue than most surface animals require to undergo in the course of an entire day.

In nature we find that the resource of every creature is in very exact proportion to the necessities of that creature; and this law is as perfect in the mole, obscurely labouring under ground, as it is in those gay children of the sun which wanton in the brightness of the tropical day. The adaptation requires two parts: there must be organs fitted for the work which is to be performed, and there must be the requisite impulse to use those organs. In both these respects the mole is a perfect model of nature's workmanship. Its organisation is more complete in what may be

called dead strength than the organisation of any other animal with which we are acquainted; and the appetites which impel it to labour, and the senses which direct it in its labours, are of a very high order. We have already said that the cravings of hunger in the mole are frequent and violent, beyond all example in animated nature; and it will immediately be seen that, in an animal which has to bore for perhaps several yards through the solid earth in order to procure a single worm, this very strong impulse is necessary for putting it into motion. But the impulse is only as it were the mere beginning—the stimulating cause of the mole's operations. It is essential, and without it the guides and the organs of working would be vain and useless, but so would it be an idle torment to the animal without them. In considering only its underground operations, sight would be of little use to the mole, though, as we shall afterwards have occasion more particularly to remark, there are seasons and situations where the use of this sense becomes necessary to the common mole. Smelling and hearing are the two senses which are most essential to an animal living under ground, and digging along the solid earth for its food: and it is perhaps no exaggeration to say that in both of these senses the mole is more highly endowed than any other animal with which we are acquainted. It is probable, indeed, that there is in this animal a more general sense than either of these two, and one which, as it has not "a local habitation" in any specific part of the animal, has not "a name" in the vocabularies of describers. But, notwithstanding this, the existence of the sense is not in the least doubtful. The fur of the mole is the most delicate, and the most abundant, surface for surface, which is found on any animal. Fur of every kind may be regarded as a species of organ of what is called touch, not in the mere pile of the fur certainly, but in the sensation which is instantly communicated to the root of the fur, as we find in many animals, and especially in those whiskers of nocturnal animals which guide them in their rambles. Upon the same principle there is no question that the exquisitely delicate fur of the mole, which yields to a touch quite imperceptible by us, is one of the finest organs of feeling in the whole animal kingdom. Nor is there any doubt that this fur communicates to the owner the slightest concussion of the earth over its nest or its gallery, without any assistance from the allocated senses of hearing and smelling, how acute soever they may be for their particular purposes. The produced nose of the mole, and the large development of the olfactory nerves, are proofs that its sense of smelling is exceedingly keen; and, though an external concha or shell to the ear would be an incumbrance to it in its operations, there is no doubt that its hearing is very acute, for its internal ear is remarkably well formed. This, however, is a portion of the physiology of animals upon which we require to exercise no ordinary degree of caution. In all cases we are apt to take ourselves as models; and, as we are adapted only for the exercise of our senses in the free air, we are very apt to judge in our manner of those animals which dwell in the waters or in the earth, and as such have very different media through which impressions are communicated to them. In consequence of this we are very apt to impute to some single sense having specific organs and a local situation, that impression which is in reality conveyed to the whole body of an animal by the element in which that animal resides.

It is not easy to form a correct estimate of the senses of the mole by any analogy drawn from animals which inhabit the free air and enjoy the light; and as we are apt, in all our judgments of animals, to carry this analogy along with us as the standard of our judgment, we are apt to err in the case of so very singular an animal as the mole, unless we use the greatest caution, and throw the case upon its own individual facts—a mode of proceeding which is most essential to the naturalist in evidence.

That the mole possesses senses different from those of animals which live above ground and enjoy the light, is undoubted; but what those senses are, it is impossible for us to determine to a minute shade. We call them hearing and smelling, and there is no question that both of these senses are very acute in the mole. It really seems, however, that naturalists, even those of most commendable zeal and ability, are apt to lay too much stress upon those localised senses, and to neglect, or leave out of their estimate, that more general, and, as one would say, more primary sense, which belongs to the whole frame of the animal, and not to any particular organ. This is the “muscular feeling,” of which some account will be found in the article *MAMMALIA*; and as it is the real foundation of every species of animal feeling and perception, whatever may be its immediate organ, we ought to make it the very foundation of all our speculations and judgments with regard to the senses of animals, whatever may be the form and development of the organs of those senses. We have already remarked, that the fur of the mole is well adapted for communicating every species of impression to the system of the animal; and we may now add, that the naked parts of it appear to be fitted for the same purpose. It is true, that the snout of the mole is cartilaginous, and that the under sides of the paws are covered with callous rather than a delicate and flexible skin. But these are matters of minor importance, because the fact of feeling depends not upon the mere external part so much as on the internal one with which that is connected. We have a striking example of this in the ox. A blow on the horn of that animal, though it does not of course inflict any pain, and not in the case of a mere blow any injury upon the horn, is yet more severely felt, and causes more acute anguish to the animal, than a blow with the same instrument, and struck with the same force, upon the muscular parts. It is indeed a remarkable fact that the muscles of animals, which are pre-eminently their working structures, are really the parts which suffer the least from blows and bruises, and that tendon, and especially the periosteum of bone, are vastly more sensitive than flesh. Knowing these facts, and it is necessary that every student of nature should know them, we must be cautious before we come to any positive or general decision as to what part of an animal can, and what cannot, feel acutely. Upon this principle it is highly probable that the callous skin of the mole, and even the roots of its paws, large and hard as those organs are, conspire with the fur, and the organs of hearing and smelling, in helping the animal to delve its subterraneous way after its food. Still there is something very curious in the matter. The larvæ of the ground insects, that is, those of the cockchafer and others, which are so exceedingly destructive to vegetation in fields and meadows, do not appear to be possessed of much sensibility, and therefore it is natural to suppose that the

mole should be able to come upon them unawares. The earth-worm is, however, an exceedingly sentient creature, both as respects changes of the atmosphere and concussions of the earth. Heat and cold, drought and moisture, the beating of the earth, the tread of a heavy animal, and almost anything which produces a change or a disturbance, puts the earth-worms in motion. It is therefore not a little singular that these very earth-worms should form the principal food of the mole, and that it should obtain a sufficient number of them to repay the labour of its digging a mine after them in the earth. To this mine we shall afterwards have occasion to revert, and we shall then remark on the curious similarity which there is between the mining of moles and the mining of colliers; but we are in the mean time speaking of the general habits of the animal, and its general adaptation to that singular place which is assigned it in nature.

From the time of Aristotle downward there have been mistakes respecting the sense of sight in the mole. There is no question of the accuracy of all that is stated by Aristotle respecting every animal which came under his observation, and perhaps he is more to be relied upon than any naturalist of the long period which intervened between him and our illustrious countryman, Ray. There is, however, one caution to which we must carefully attend if we would avail ourselves of the accuracy of the great Grecian naturalist; and this caution is especially necessary in the case of the mole. In Italy, in Greece, and in other parts of the south of Europe, there is a mole resembling the common mole in form and manners, but which is to all appearance blind. It has eyes, indeed, but they are the most rudimental eyes with which we are acquainted, being not larger than grains of mustard-seed, and having the skin over them without the slightest separation or opening of eyelids. It is true that we are not warranted in predicating absolute blindness of the animal, even in this case; because it is impossible for us to state precisely the degree of development which is necessary before an eye can see. We know that if a well-developed eye which is habitually used in daylight were to be reduced to the state of the eyes of this southern mole, it could not by possibility see; but still this gives us no positive criterion as to the quantity of development in an eye which is absolutely necessary for the function of vision. Thus we are thrown upon the facts of the particular case; and experiment has clearly decided that the common mole not only sees, but sees well, though in the case of the mole of the south of Europe, which has no external opening to the eyes, the fact has not been decided.

There is a passage in Shakspeare's *Romeo and Juliet*, which has been quoted by almost every describer of the mole since the time which Shakspeare wrote. But, notwithstanding the number of times that this short passage has been quoted, we shall quote it again for the purpose of doing justice both to the mole and to Shakspeare. How he came by it is not for us to say; but it is certain that Shakspeare was acquainted with a fact in natural history of which professed naturalists were ignorant for a long time after his death. The passage to which we allude is as follows:—

“Pray you, tread softly, that the *blind* mole may not
Hear a foot fall!”

The scene of this passage is laid in the neighbour-

hood of Venice, and the mole of that country is the blind one; but how he came to know that the moles of that country have the eyelids unopened is a question which we cannot solve. The probability is that, like most others, he had taken his notions of the animal from the description of Aristotle, or rather from the popular opinions grounded upon that description; and that, as Aristotle described this blind or southern mole, the mole of authors and also of popular story, in the time of Aristotle, was the southern mole, and not the common mole as found in this country; for our mole has not only eyes, but very brilliant ones, though they are very small.

That the mole of the more temperate and cold districts of Europe should have its eyes capable of being opened, and that the mole of the warmer parts should not, is a curious fact in the physiology of the two animals; and we believe that there is a corresponding difference in the habits of the animals. The southern mole, or blind mole, as it may be called in contradistinction to the other, is never, we believe, found on the surface. The soil of the Apennines, where it is understood to be more abundant than anywhere else, is always full of worms, of larvæ, of ground insects, or of all of them, and therefore the mole finds under ground a constant supply for its voracious appetite, and consequently it is never forced to come to the surface. Our mole, on the other hand, is sometimes starved out in its subterranean pastures, and compelled to come to the surface to feed upon what it can find there. When above ground it is rather dexterous in the capture of the smaller rodentia, and even of birds, which it tears open and devours with the greatest voracity. Indeed its ultimate attack upon them is an effort of frenzy, comparable on a small scale to the spring of the lion or the tiger, and if once it can lay hold, there is scarcely any possibility of shaking it off. Birds, when it can surprise them, are an easy prey, and so are the different species of field-mice. Rats are, however, more untoward customers; and, though a hungry mole very readily attacks a rat, the rat defends itself so stoutly that the battle is usually a drawn one, or rather it is more a matter of chance than of superiority which shall gain the day, for they never desist until one is killed, and whichever may be the victim, the vanquished is eaten as a matter of course. Those surface excursions of the mole are usually performed during the night. This, however, is not always the case; for the appetite of the mole goads it on so forcibly, that it will brave all circumstances in order that it may feed. Hence, at peculiar seasons, especially when the autumnal droughts have sent the worms far below the surface, the mole is often found prowling about in daylight. It proceeds stealthily through the grass, in consequence of the softness of its fur and the slowness of its motions upon a level surface, and therefore it is not often seen by human beings. Dogs of keen scent find it out however; and sportsmen, especially if their pointers are not highly bred, are sometimes apt to find them standing at a mole instead of more noble game.

The fact of the mole standing alone in its economy (for, with the exception of the blindness alluded to, there is hardly any difference between the two species), it is one of the most interesting animals in the whole class of the mammalia. It is one which certainly disfigures the surface of the ground, and spoils many of the operations of the farmer and the gardener.

At the same time we must not come to too hasty a judgment against it on the whole. In wild nature there is no question that it is an exceedingly useful animal, and it is very doubtful whether the persecution with which it meets in cultivated places is altogether judicious. There is no doubt that human cultivation by being artificial, in a great measure alters the state of things, so that many of the children of simple nature, which are very necessary there, are not required, or even become nuisances where man cultivates. Still, it must be borne in mind that cultivation can never be rendered wholly artificial; but that whatever man does in the way of art, he must still leave far more to be done by nature. This consideration ought to give him a feeling for all that is natural about him, and make him consider well whether he may not destroy any species of animal beyond the limit to which his artificial cultivation extends; for if he does this he may rest assured that he is destroying the balance of nature, and thereby doing a mischief to himself.

There is no doubt that the portion of full-grown vegetables, and also of those in a moderately advanced stage of their growth which is in the ground, is much smaller than that which is in the air; but, excepting in those countries where the mole is not wanted, and therefore not to be found, the portion of the vegetable which is in the soil is most essential to it, and without it the portion above the surface would instantly perish. In such places, too, the beginning of all vegetation is in the soil; and though nature has adapted matters so beautifully, that, generally speaking, the insect tribes are dormant at the season when the seeds of vegetables are sprouting, yet there are some which germinate at the time when insects, more especially the ground larvæ, which are exceedingly voracious, are in full activity. The roots of young vegetables, and the young rootlings of old vegetables, being blanched by their covering of mould, are the most succulent parts of the plants, and therefore the parts which hold out the greatest temptation to those predatory insects. The rook, and some other surface feeders, render great service to man in the destruction of these subterranean spoilers; but the service which they render is, as a matter of necessity, confined to the larger plants, which give indication above ground of the spoiler that is attacking them below. This takes place chiefly in the cultivated lands, and not in the rich grassy meadows, the turf of which is, on some occasions, so completely cut by the larvæ of the cockchafer, as that many square yards of it, not more than an inch thick, may be rolled up like a blanket. The places where such depredations occur are the favourite hunting grounds of the mole; and although, in the course of its hunting, that animal disfigures the surface, by throwing up little mounds of earth here and there, there is no question that it renders the most essential service to vegetation by the destruction of the small animals upon which it feeds. On many points of natural history we are in some danger of being guilty of what is usually called a *hippolytism*, or putting the cart before the horse, and making the cause and the effect change places; yet, when we find two circumstances always in close juxtaposition, though we cannot decide positively which is cause and which is effect, we may generally conclude that there is a reciprocal advantage, and that the one is necessary to the other. Now, we find that there is

no mole in the barren grounds, or in grounds which are so habitually sour that they have a constant tendency to be covered with moss, to the destruction of more kindly vegetation. We do not find the mole in any situation where the soil is very thin; and when man habitually turns the soil, either with the plough or with the spade, the mole departs, as if conscious that its labours are not wanted. Wherever we find mole-heaps, mole-hills, and mole-runs, there is invariably richer grass upon the surface than there is in places which the animal never visits. We do not mean to say that the mole is in any respect the cause of the superior fertility of those places in which it is found; but the mole is chiefly, if not exclusively, an animal-feeder; the animals upon which it feeds all subsist upon the roots or buried seeds of vegetables (for there is nothing else accessible to them); and therefore the mole must, from the incessant craving of its appetite, destroy a vast number of those spoilers. Whether the disfiguring of the surface, which results from the labours of the animal, is or is not compensated by its labours in the cultivated field, we do not take upon us to determine; but it is certain that, in wild nature, the mole is, in temperate climates, a grand conservator of the more kindly vegetables; and, as it is one of the most singular of the mammalia, it is at the same time one of the most useful. The mole is, in fact, placed under such peculiar circumstances, endowed with powers so singular and so great in proportion to the volume of its body, and furnished with so strong an impulse to activity, that obscure as it is in its dwelling and its operations, the judgment of sound philosophy would dispose us to set it down as almost the very *chef-d'œuvre* of all the mammalia. On this account, and also because the animal is both despised and persecuted, we shall enter somewhat more largely into the consideration of it than we have done into that of more showy and sunward animals. This account, in order to make it perfect, will require some systematic arrangement. We shall not formally divide it into sections; but the following is the order in which the different parts of the description most naturally present themselves to our consideration:—First, the organs of nutrition, which determine the character of the animal; secondly, the organs of locomotion, which point out its adaptation to the place which it occupies in nature; thirdly, the organs of sense, which conspire with the former; fourthly, the organs of reproduction, which are so peculiar that we cannot, in justice to the subject, pass them entirely in silence, though we shall touch upon them with that lightness and delicacy which ought to characterise a work intended not so much for professional naturalists as for general readers; and, fifthly, the manners of the animal, more especially in the construction of its place of abode, its grand subterranean passages, and the more temporary mines in which it seeks its food. In all these we may take the details on the general description rather than on the distinctive notice of the two species, inasmuch as the manners of both species do not appear to differ much, except in so far as they are modified by climate.

In considering the organs of nutrition in any animal, the teeth claim our first and principal attention, because more depends on them than on any other part of the organisation; and if we study them well, they enable us to determine the quality, and even to form a tolerable estimate of the quantity of food

which the animal requires. It is upon this principle that Cuvier, the most philosophic of naturalists, founded his classification of animals upon the teeth, in every case in which it was possible so to found; and it is worthy of remark, that, whenever circumstances compelled him to abandon this character, and have recourse to another one, the classification is loose and imperfect, and it becomes impossible to arrive at any knowledge of the individual genera from the characters given to the order. Upon referring to the article MAMMALIA in this work, the reader will at once see that this is remarkably the case in the order *Edentata*, in which the character, as dependent on the teeth, is negative, and more especially in the *Pachydermata*, in which the distinctive character of the order has no reference to the teeth.

The mole is one of those animals which possesses the greatest number of teeth; and though the analogy is not perhaps absolutely perfect throughout the whole system, as indeed no analogy of nature discoverable by us can be, still it is true that the voracity of every animal increases in proportion as its teeth are more numerous, whatever may be the structure of those teeth, or the nature of the food for the prehension and preparation of which they are adapted. The mole has eleven teeth in each side of both jaws, and consequently forty-four in the whole, which is a greater number than is possessed by the most formidable of the regular carnivora. Counting them from the middle of the front, there are on each side of the upper jaw three incisors, one canine, and seven grinders, of which three are true, and four in advance of them false. The incisors are small, but they are arranged with great regularity, so that, in their edges, they are as keen and trenchant as knives. The canines are very strong; they stand much out, and they are planted in the jaw with great firmness by means of two roots, the anterior of which is by much the larger of the two, and goes very deeply into the jaw—so deeply, indeed, that its extremity reaches the nasal bone, which is placed as a sort of key-stone between the fangs or roots of those teeth on the two sides. This structure of the canines gives them a very powerful hold, inasmuch as the deeply-inserted anterior fang is the point upon which the tooth would turn, and the tooth will not turn upon this point without an absolute fracture of the jaw of the animal. It is in consequence of this that, when the mole once fastens, it cannot be made to quit its hold unless its jaws are absolutely broken, or some severe injuries inflicted on its head. The three foremost false molars are small, leaving room for the canine tooth to take effect; but the fourth one is large, trenchant in the edge, and approaching more nearly to the form of a true carnivorous tooth than the cheek-tooth of almost any other insectivorous mammalia. The true grinders differ little from those of the other insectivorous carnassiers, only the points with which their crowns are beset are particularly sharp. The teeth in the lower jaw are the same in number as those in the upper, but they are different in their arrangement. Here, then, are four incisives on each side, with one canine, and six molars, of which three are false and three true. There is indeed some uncertainty about the system of dentition in this lower jaw, some comparative anatomists being of opinion that the last incisive tooth of the four is really the canine, and others being of opinion

that this character belongs to the tooth immediately behind it. The fact is, that, though the teeth in the lower jaw are of a highly treacherous, and even carnivorous character, there does not appear to be among them anything which can be decidedly called a canine tooth in the proper sense of the term. This is rather a curious circumstance in the mouth of the mole, inasmuch as the rest of its teeth are of a more carnivorous character than those of any others of the insectivorous mammalia. In consequence of this formation of the teeth, the mole does not kill its prey, when that prey is warm-blooded, by one decisive bite, as is the case with the regular carnivora. Its great strength, and the powerful cross motion which it has in its fore paws, enable it to master the prey, and hold it down; and the first wound which it inflicts is that of tearing open the belly of the victim, and devouring its vitals. Though it has been sometimes said that the mole will occasionally feed upon farinaceous roots, such a mode of feeding is by no means probable, inasmuch as the digestive organs of the animal are wholly of a carnivorous character. The stomach is indeed large for the size of the animal, but it is membranous, and the intestines have not even a vestige of a cæcal appendage, which is rarely, if ever, wanting in vegetable feeders. Besides the smaller inhabitants below the surface of the earth, and mice, and occasional birds, the mole has no hesitation in despatching frogs and newts, and perhaps even the smaller snakes; but it has been well ascertained that it will not attack a toad, even though reduced to the utmost extremity by that hunger of which it is so impatient. The cause of this seems to be the peculiar secretion given out by the skin of the toad, which protects that most harmless and inoffensive of animals from the attacks of almost every foe. This secretion is exceedingly acrid, and thus it repels even the hungry mole, which is, without question, the most voracious of all animals. Still moles find abundance of food. When seen, they are always in good condition; and in places which are suited to them they are very numerous, notwithstanding the labours of human mole-catchers, and the disposition which the animals have to prey upon each other. This disposition is so great, that two moles of the same sex, or even of different sexes, except at a particular season, cannot meet without a combat, which invariably ends in the devouring of the weaker one by the stronger. It should seem that there is some provision with regard to this in the runs or highways which the moles make, for these are always so constructed as that only one mole can pass along; and though the same common path is sometimes used by several of them, the weaker ones always contrive to escape into a side-gallery when they find the stronger advancing upon them; and, as no animal absolutely hunts its own species as regular prey, they by this means make their escape.

The organs of motion in the moles are as peculiar and characteristic as any others of their system. The general form of the feet, and their adaptation to the subterranean operations of the animals, have been partially alluded to in a general way in the article MAMMALIA. It will be necessary, however, to advert to them somewhat more in detail, in order to enable the reader to form a correct estimate of this most singular of all European mammalia. The mole may be considered as the most perfect type of digging animals; and there is no other genus which is so

admirably fitted for making its way under ground. The anterior extremities—that is, the fore paws, or hands, as we may term them—are differently placed and articulated from those of every other animal. They are placed more in advance or nearer the head than in other animals; they are very short, but firm, in all their individual bones; and they are provided with very powerful muscles. The blade-bone is long and slender, presenting some vestiges of spinous processes, by means of which it has much more firm imbedment in the flesh. The clavicle is also both long and strong, and projects forward, so that the shoulder-joint, or articulation of the humerus, advances to nearly the middle of the neck; and while this structure enables the fore paws to act more in advance than if the shoulder-joint were placed as in the other mammalia, it at the same time furnishes the neck with a support on each side, by means of which the pointed and cartilaginous muzzle can bore through the soil with rapidity and certainty. The humerus is of a very peculiar structure, appearing as if the round or medial part were obliterated, and the two ends of the bone brought close upon each other. The radius is short, but very stout, entirely separated from the cubitus; and the olecranal process projects as far as the articulation of the arm with the fore arm, or that which answers to the elbow-joint in man. The bones which form the hand are very finely constructed. With the exception of the last phalanges which carry the nails, the bones are all remarkably short; and though the upper joints have much motion, the under ones are stiff and firm, and the hand cannot be bent backwards even to a straight line. The palm or flat of the hand, or fore paw, is turned upwards; so that, when the mole digs, the earth which it removes is not thrown under the belly of the animal, as is the case in those animals which dig by the downward action of the feet in a direction parallel to a mesial plane. It is thrown upwards; and, as the hands really work in advance of the thick part of the head and body, it is really thrown forwards; and when it accumulates in such quantity as to impede the operations of the animal, it is forced to the surface in those little heaps which are usually found marking the course of moles on their feeding grounds. These little heaps, which consist of earth simply thrown out of the way of the animal as lumber, must not be confounded with the permanent mole-hill afterwards to be spoken of, which is a much more curious and elaborate structure; neither must the fresh heaps which are seen on the feeding ground be considered as indicating the position of the permanent galleries, along which the mole passes and repasses, and in which alone it can be taken. In those temporary openings which are made in the operation of feeding, it would be in vain to set a mole-trap; because the mole never passes them a second time, though they are generally at no great distance from a permanent gallery. The fore paws of the mole bear some slight resemblance to the hands of the human subject; but this resemblance is very slight, as the thumb and fingers act in the same direction, and the paw in its general shape bears some resemblance to a pointed shovel, the most effective instrument for at once dividing and removing the soil. The last bones are entirely incased with large claws, and the principal bend of which the hand is susceptible is the joints of those, by means of which the claws are brought so as to form rather less than a

right angle with the palm and direction of the fore arm. The mole is not seen when vigorously at work, because it works under ground; but there is no doubt that it works with the claws bent in this angular manner, because it is the position in which they can act with the greatest effect. Indeed it is not possible to imagine an instrument better fitted for its work than this is, and it would make the very best model for a hoe.

The hind legs of the mole have five toes and five long claws on the feet, as well as the fore ones; and they are well adapted for digging; but in other respects their structure is not so peculiar as that of the others. The bones of the pelvis are exceedingly narrow, and the fore or under part of the pelvis is open, so that in the female the young do not pass in the same manner as they do in the more typical mammalia. There are certain other peculiarities in the system of reproduction, especially in the female mole, which are highly interesting in a physiological point of view; but they can hardly be described in a way which would interest the general reader. We may mention, however, that the female has three openings to the body, one of which is so completely closed in the young state that there is no distinguishing the young male from the young female, except by internal dissection. Both are readily taken for males, and this is the point which it is desirable that common observers should know, because want of attention to it has probably led to some erroneous conclusions with regard to the relative numbers of the sexes. Most authors who treat on the mole concur in stating that the number of females is very small as compared with that of males. To a certain extent this is probably the case, but it is doubtful whether there be any animal in which the number of males so greatly predominates over that of females as is alleged of the mole. Moles are monogamous, in as far as the males are concerned; and the females are not only monandrous, but they are so reluctant to associate that they have to be taken by efforts as desperate as those which wived the Roman brigands to the Sabine women. In those animals which have the male polygamous, the females are all much more numerous than the males; and we are not aware that in any species of animal the female can be correctly described as polyandrous. In nature we never find a disproportion of the two sexes, without there being some purpose which it answers; and it is not easy to say what purpose of this kind could be answered by a great excess of male moles above females. We shall, however, have occasion very slightly to notice "the loves of the moles," which in the describable part of them are different from those of all other creatures; and so we may now content ourselves with holding up the disparity of the sexes as a point not completely established. There is another point which renders the distinction of male and female moles a matter of some difficulty. The mammae of the females bear some slight resemblance to those of the marsupial animals, inasmuch as they are hardly visible, except when required for the use of the young. The young too are produced in a very immature state, though certainly not rudimental, like those of marsupial animals. There is no doubt that those peculiarities in the structure of the female are given to her for the purpose of adapting her for seeking her food when in the gravid state; for she must provide for herself and her young without any assistance from the other sex.

Of the organs of sense we have already partially spoken. There is little doubt that, of the senses allocated to particular organs, smelling is the most acute, and the one upon which the animal chiefly depends for finding out that food, the capture of which is so laborious, and the appetite so perfectly ravenous. The extremity of the snout is drawn out into two cartilaginous tubes, which lead to various cells, thickly ramified with the olfactory nerves. This snout, however, has various other functions to perform. It opens the earth, and guides the motions of the animal in digging; it throws up the earth to the surface, when it accumulates in such quantity as to impede the operation of digging; it appears to be an organ of touch; and it is to some extent prehensile, and assists the animal in capturing its food, or in forcing it to the mouth, which is far under this curious organ. There is no question that the hearing, considered merely as a local sense, and without reference to the general sensibility of the body, is very acute; for, though there is no external ear, the interior is both ample and well developed.

Thus, in respect of three of its senses, we must regard the mole as being not inferior to any other animal. In respect of smell, it must indeed be the most acute of any, because of the element through which it has to bore in quest of the greater part of its food. It is well known that nothing tends so much to intercept or take off odours of all kinds, and more especially animal odours, than fresh mould, of that rich and loamy nature which forms the richest pasture of the mole. So well is this known, that those people of inhospitable climates, who are constrained to live in great part upon sea-birds, whose flesh is rank, contrive to sweeten it by burying it in the soil. The mole has necessarily to contend against this disadvantage of its pastures; and, as no production of nature is left deficient for the ordinary overcoming of any difficulty or hardship that may lie in its way, we may conclude, as a matter of course, that there is a keenness of scent in the mole far surpassing that of any animal which feeds on the surface of the earth. The hearing we cannot so well understand, because we have no good instance of the effect of hearing when both the sounding body and the hearing ear are in the earth. It is highly probable, however, from the great development of the labyrinth of the ear, that the sense of hearing is exceedingly acute as well as that of smell. That the sight is much less so is true, though the common mole is not blind; but it has no use for eyes in its subterranean occupations, which consume the greater part of its time; and as nature is never prodigal any more than stinted, eyes to the mole as fully developed as those of surface animals would be contrary to the general law. We have already mentioned the mistake in which the alleged blindness of the common mole has in all probability originated; and we shall now add that the little eyes which it possesses are remarkable for their brightness, as well as for the apparent perfection of their structure. When examined in profile, the cornea or anterior coat of the eye is remarkably convex and highly transparent, but blackish grey when viewed in front. The interior coats are deep black, and the retina is very finely developed. The crystalline lens is very convex as well as the cornea, which would lead one to conclude that the mole has eyes of very short focal length, and which consequently see very acutely within their range.

What may be the difference in manners between the blind mole of the south, which has the eyelids closed, and our common mole, it is impossible to say, as very little is known respecting the former. There must be a difference, however, and analogy would lead us to suppose that the blind mole remains much more habitually under ground than the common one. There are various causes which compel the common mole to be a surface-walker, and even a swimmer, at which latter operation it is by no means inexpert; and when it swims, its glossy fur takes down little air bubbles, which sparkle like pearls through the water, in the same manner as those on the fur of the water-shrews. This power of swimming is absolutely indispensable to the animal, because it runs under ground yet flooded during rains; and there are instances in which the failure of food to supply its ungovernable appetite compels it to cross streams of considerable breadth. In the summer drought it is reduced to equal straits, for many of the larvæ are then on the wing, the worms are down below its depth, and the ground is too much consolidated for its working along with the requisite degree of speed. It is at such times that the mole is found on the surface, but never exposed to the full light of the sun. At such times it feeds on mice and ground birds, the first of which are out of their holes, and the second are reposing on the ground by the time that the evening twilight gets dusky. The mole has thus an opportunity of exercising its powers as a surface hunter, and also of obtaining a full meal with less labour than is required to procure it a scanty one under ground. It is true that it often perishes of hunger, or of hunger and rage jointly, before it can meet with a mouse or a bird; but, if it does scent the one or the other, it is a crafty, a daring, and, generally speaking, a successful hunter. It proceeds upon the scent, gliding so softly through the grass that it makes neither rustle nor foot-fall until it is close upon its victim, and then it finishes its work in a perfect paroxysm of energy.

Intense energy, in every sense in which the words can be used, is indeed the character of the mole, and it possesses this in a higher degree than any known animal. This demands a powerful stimulus and efficient organs for execution, and we have seen that the mole is furnished with these in an extreme degree. All its movements indeed, and all its operations indicate an excess of animation, and that in an animal which in our common speech we set down as having little or none. The one of these parts of its economy not only requires, but necessarily involves, the other. The food could not be acquired by such labour as a mole has to perform, were it not for the great energy and strength of the animal; and the energy and strength could not be kept up without the copious supply of food. It is doubtful, indeed, whether such an animal as the mole could exist habitually on the surface of the earth, and exposed to the vicissitudes of the weather. The supply of an animal must, in every case, be equal to the waste, and exposure to vicissitudes of weather is a much greater source of waste than one would be apt to suppose, as we find that animals freely exposed to the open air, even though spared the labour of finding their food, do not fatten so readily, or to the extent of those which are sheltered. Now, in its common habits, the mole may be said to be always sheltered, with very little variation of temperature, and in a situation where there can be

comparatively little drain upon it from the action of the atmosphere. Thus we see that the place which has been assigned to the mole in nature, humble and grovelling as we deem it, is highly favourable to the development and the maintenance of its animal powers.

There is another point very strongly established by the economy of the mole, and that is the connexion between great energy of living power and the easy destruction of the same. The mole, notwithstanding the quality which we have mentioned, perishes of hunger sooner than any other creature, and less exposure or contingency of any kind is fatal to it.

The habitation and general mode of action in the mole are well worthy of study. Except at pairing time, and that is of brief duration, moles are strictly solitary, and each one has its own stronghold or castle. This is very elaborately constructed, and generally placed against a wall, near the roots of a tree, or in some place where it is in part sheltered. It rises with a dome in the form of a conicle, and having the base three or four times as great as the altitude above the surface, into which it gradually fines off so as to drain off the water, and it is so hard and firm that none can penetrate through. The interior consists of two galleries nearly circular, and a circular habitation within. The lower gallery, which has by much the greatest diameter, is placed nearly on a level with the surface of the ground, and the upper one about midway between the lower and the top of the dome: five or six sloping passages lead from the one gallery to the other, and at least three lead from the upper gallery to the nest or habitation, which is placed below the upper gallery, but rather above the lower one. Those galleries and passages are not formed by removing the earth and throwing it on the surface, as the mole does when it hunts. They are, as one would say, bored in the solid earth, without the removal of any part of the materials. In consequence of this they are smooth and hard, and not liable to be filled up or be disturbed as the animal moves along. The passages between the galleries, and also those which lead to the nest, are ingeniously placed, so that one of them never opens opposite the entrance of another; and in this way the castle and its outworks are quite a labyrinth to all but the builder and proprietor. This very ingenious and very elaborate structure is understood to be made in the latter part of summer, and the mole makes it its regular home and resting-place from the time of the autumnal rains until the warm season again sets in. It is generally said that a new one is made in a different place every year; and, though it is impossible to establish the fact in all cases, this is by no means improbable, because the labours of a mole are carried on with so much vigour and perseverance, that it is sufficient to exhaust a considerable space of all the underground prey which it contains in the course of one season. Much must, no doubt, however, depend on the extent and nature of the pasture. There is one peculiarity of the mole's habitation which we have forgotten to mention, and to which there is something similar in the burrow of the marmot: immediately under the nest there descends a passage more free at its entrance than any of the others. This curves downward to a depth nearly equal to the height of the dome, and then curves upward again at a little distance from the nest. The precise use of this is

not known; but it may serve either as a sally-port or as a means of drainage.

We shall suppose the fort constructed in the manner that has been stated; but, even though it is, the labours of the animal may be said to be little else than begun, unless, indeed, the castle is constructed upon, or closely adjoining, a previously-made run, which is almost always the case where moles are numerous, and occupy a considerable breadth of ground. There is one main thoroughfare or highway, which is either the one by which the mole arrives at and constructs the castle, or one made leading from it; generally, we believe, it is the former, unless where a mole breaks ground in a new place altogether. Besides this, there are other galleries branching out in all directions from the habitation, generally ramified into new branches after a little distance, and very often bending round until they come into the main road or roads. Some of these are sufficiently near the surface for the mole to throw up heaps at least in the first formation of them; and others are too deep for this; but in all cases of a second passage along the same gallery the body of the animal smooths it, and converts it into a permanent passage. Those passages cross and meet each other in a variety of directions, and those of one mole not unfrequently cross those of another. It does not appear that, even when there is this kind of territorial interference, the one mole wages voluntary battle upon the other; but, if two happen to meet, there is a mortal combat, and no quarter.

The feeding of the mole is in new runs opened up from one or another of these galleries, and thus its distance from the castle always becomes greater and greater, while the intermediate ground is mined in all directions. There is thus a very considerable resemblance between the working of a mole under ground and the working of a coal-mine by narrow galleries; but whether the directors of coal-mining ever studied the under-ground plan of the mole, it is impossible to say.

The degree of strength which the mole gives to its habitation is always very nicely proportioned to the degree of danger to which it is exposed. In safe and secluded places the crown of the dome is only a few inches thick, while in exposed ones it is a foot or more. It is the same with the main roads, and all the galleries which are used as permanent passages. The instinct which regulates those adaptations is a very curious one, and quite inexplicable upon any principle with which we are acquainted. That it depends upon anything like a knowledge of the circumstances on the part of the animal, in any way analogous to our knowledge, cannot possibly be true; and therefore, as is the case with all that we call animal instincts, it is impossible for us to explain it upon any principles of our philosophy. The very word instinct might tell us this, and thus spare us the idleness of wondering about it; because the real meaning of instinct is that which proceeds entirely from the animal itself, and to the cause of which we have therefore no clue, though we may observe the phenomena. It has often been observed that when a mole carries its gallery against the foundation of a wall, a large stone, or any other obstacle through which it cannot make way, it turns downwards, upwards, or to a side, according to circumstances; and that, when it crosses a footpath, it mines more deeply than when it is approaching or leaving such a

situation. We have even heard it said that moles work more deeply in places pastured by cattle than in those pastured by sheep; but we cannot vouch for the truth of its instinct extending to this extraordinary length. Its instincts are so curious, however, and impressions are made on its senses by means so different from those that affect us, that our judgments respecting it must, in all cases, remain very imperfect.

The size of the galleries, even the principal ones, which connect the castle with the most remote pastures, are never so large as to admit two moles, though they are always such that a single one can move freely along. The hunting run, from which the earth is thrown up in successive heaps, is at first no bigger than to allow the animal to squeeze itself along; and this tightness assists it in digging, by giving it a firm hold on the sides of the passage. Should the run be afterwards converted into a road, which is very frequently the case, the mole casts up no more earth, but presses the sides with its body as it goes along, and thereby gives the passage sufficient consistency for keeping it open. Of course there is an end to all hunting after the sides of the passage are thus compressed, and indeed a mole rarely hunts twice in the same run. On the contrary, its underground food is almost entirely obtained by digging anew in the earth, so that the animal has need of all its stimulating appetites. When alarmed, the mole can proceed along those main roads, which are worked smooth, with a degree of rapidity far greater than one would suppose, if the fact had not been established experimentally by an author of undoubted veracity. M. Henri le Court, who was driven from Paris by the horrors of the French revolution, retired to the country, and observed nature with the same earnestness and the same unobtrusive quietness as our illustrious Gilbert White; and it is a fact worth mentioning that the great Ray himself studied nature when in retirement from political persecution. The French naturalist above mentioned paid particular attention to the natural history of the mole, and was the first who threw much light on its habits, or elevated it to that rank which it is entitled to hold among the productions of nature. The method upon which he fell to ascertain the full speed of the mole was very ingenious. He found a mole road of considerable length, into which he placed straws, intersecting the passage perpendicularly, and placed on the tops of them, above ground, little flags of paper. When all was ready for measuring the time, and he had ascertained that the mole was in the road, he went to a horn which he had placed in the road more distant from the mole's castle, and then, "winding the horn with a hideous cry," as Geoffroy St. Hilaire says, he sent the mole post haste to its castle, leaving the worms to their fate. On comparing the time and distance, it was ascertained that the speed of the mole was nearly the same as that of an ordinary horse trotting; from which it should seem that the passion of fear operates as powerfully on the mole as the passion of hunger; and this still farther establishes the character we have endeavoured to show that it possesses of intense energy in all its animal action. Whether it may run as fast at other times we have no means of ascertaining; but certainly its motion on the surface of the ground is very slow as compared with this. Along the run, when at this velocity, its mode of action cannot be seen; but it is understood to be a very curious kind of gallop,

in which the feet, instead of striking under the body of the animal, strike outwards laterally against the concave sides of the run; and, from the distance between the feeding-ground and the castle, it is highly probable that the mole has often to travel over as much distance in the course of a day as a larger animal grazing a rich pasture. At the times when the hunger of the mole is satisfied it retires to its castle, or other place of repose, and is understood to remain about five hours in profound sleep after it has had a very full meal; and when this sleep is over it returns to its severe labour with the same violent energy as before. It does not sleep on the cold earth, but forms for itself a snug bed of dried vegetable matter, or sometimes of green leaves; but it does not appear in any case to feed upon even the most succulent roots of vegetables; for whenever a mole, in a state of captivity, has had only this kind of food presented to it, it has invariably died of hunger.

The time of reproduction varies a good deal with the season; for moles are so very sensitive, that a warm season and a cold one, or a wet and a dry, will cause them to differ a good many weeks; and there is a great difference in the time of their production in the more northerly and southerly latitudes which they inhabit. February is understood to be the average pairing time in the warm places of England, two months the time of gestation, and consequently the time of production April; but, owing to the susceptibility of the animals to temperature, the young are often not produced till the summer is pretty far advanced.

As both sexes live solitary, the pairing does not take place during winter, when they keep their castles, nor until they begin to live in what may be called their summer encampments. Those encampments are more simple structures than the winter strongholds, and they are generally made near the extremity of the former year's working. The intersection of two runs, which is generally marked by an ordinary mole-hill, is chosen for this purpose, and an excavation sufficiently large for the nest is formed by throwing up fresh earth in the centre of the hill. Being at a distance from the castles, and near the unbeaten part of the feeding-ground, the moles are brought nearer to each other in their summer encampments, and it is then that the pairing takes place. At other times moles shun each other, and at these times the females are said to shun the males by every means in their power. This, however, only excites them the more, which is the true physiological cause of all this species of shunning; and, as several males are often in pursuit of the same female at the same time, desperate battles of gallantry often occur in the galleries, and many a mole is said to form a meal for his rival and mistress jointly. When one succeeds in capturing the female, he does not actually bury her in two cross roads; but he is said to drive her there, and keep her prisoner, until the cravings of hunger compel him to take his leave, after which he takes his departure, and returns no more. The female instantly begins to construct a nest for her young, generally, as is said, at the cross roads above alluded to, and she barricades those ends of them which are nearest the main roads and castles. This is said to operate as a sort of *taboo* upon all well disposed moles, for it is said to be held sacred by the rest, and that a certain portion of the pasture near it is also reserved for the female during that time when

she is least able to perform labours of the usual severity. The young vary considerably. Four or five is the number most frequently met with in a nest, but occasionally there are six, and at other times only three. It is understood that the nursing lasts till they are about half-grown, and that they are able to build castles for themselves by the autumn of the same year. Many of these circumstances are, however, a little obscure.

We shall not enter upon a question which has excited some controversy, namely, whether, upon the whole, moles do most good or harm; but in this, as in all questions of a similar nature, the whole turns upon the meaning attached to the word good; and therefore we would say with the casuist, that "in wild nature moles are good *absolute*, but among cultivated grounds and gardens they are good only *secundum quid*;" which, logically speaking, throws the argument upon the *quid*, which is the "irreducible case" in reasoning, and therefore always best left alone. That moles are useful in wild nature must be true, because they are generally distributed, and also numerous; but whether they are or are not injurious to man, as a cultivator of the ground, must depend upon the nature of the individual case. That the absence of moles does not conduce in any very high degree to the natural fertility of a country is a fact established by the case of those countries in which there are no moles. In Ireland, for instance, there are no moles, at least none which have been hitherto seen either personally or in their working; and Ireland, from enjoying more of the warm atmosphere and dripping sky of the Atlantic, ought, latitude for latitude, to possess a much more vegetating climate than Britain. Such, however, is not the fact; for whether it arises from the nature of the subsoil, from humidity, or from any other cause uninvestigated, it is unquestionable that there is in Ireland a tendency to run into moss, and ultimately into turf bog, to which there is no parallel in Britain, excepting in those high and cold places of the north which lie above or beyond the ordinary haunts of the mole. We do not mean to say that the mole is the preventive of those consequences in England; but we do mean to say that the presence of the mole is an evidence of soils fitted for growing the most kindly grasses, and that such soils are always the richer the more abundant that the moles are in them. Where the soil is cold and sour, from impenetrable understrata of clay or gravel, into which no worm can penetrate, and where water, impregnated with salts of iron, literally corrodes the surface, as it always does in such places, we never meet with a single mole-hill or run; and, if by chance a worm is found, it is blanched and tough, so as hardly to be eatable by the most hungry creature that feeds upon such food. If, indeed, one wishes to form an accurate judgment of the value of lands without trusting implicitly to the tests of land doctors, who are all more or less given to quackery, there are few better criteria than the presence or the absence of moles or mole-runs. Following the analogy of nature, which is no bad guide in such cases, we would be strongly induced to believe that, whatever it may be, there is really some connexion in usefulness between the very rich ground and the mole. In a state of nature we find them together; and as the mole, though it may disfigure the uniformity of the surface, never by any chance turns its pasture into a waste, or lessens the quantity or vigour of surface vegetation,

we are inclined to the belief that, in places in or nearly in a state of nature, the mole must be a very useful animal, whether we may be prepared or not prepared to say in what its specific use consists. The usual ground upon which its advocates take their stand is the drainage effected by its runs, and the loosening and turning up of the soil by its heaps and hills. We do not think that there is much, or anything, in either of these. They are too exclusively formed upon human contrivances for being at all applicable in wild nature. It is true that we have often seen a mole-run upon a slope discharging water like a copious spring. We also know that the earth thrown up in mole-heaps is finely pulverised, and remarkably well adapted for the renewal of garden beds, or for a top dressing to the ground in which the heaps are cast up, if spread at the proper season. Such circumstances, however, prove nothing. The water which flows off by the mole-run would very speedily run off the surface, or soak into such soil as moles work; and reducing a portion of the earth by any other means would answer just as well as the heaps. The fact is, that the mole follows the law of all the other carniassiers, and is valuable for what it consumes, not for what it does in the way of any kind of labour. It is unquestionable that the labours of the moles are valuable only in so far as they destroy the underground animals, which feed principally upon the roots of vegetables, or as they destroy the ground mice, which, however, are not so destructive, at least to the farmer, as those mice which attack corn after it is in the rick; and voracious as the moles are, and ample as is the quantity of food which a single mole requires, their structure and habits alike prevent them from performing any very important service in this way.

The enemies of the mole have generally had practice along with them; and thus, in the haunts of an expert mole-catcher, the trade of destroying them is not an unprofitable one; and there is no doubt that, under peculiar circumstances, it is useful as well as profitable. In Holland, and also in some parts of England, though to a less extent, the mole sometimes does injury by mining through dams and fences, and letting out or letting in water in places where it is not required. In such situations, and also in lawns and gardens, where it is desirable that the surface should not be disturbed, there is no question that the operations of the mole run counter to the operations of man; but in wild places, especially in woodlands, it is very probable that the operations of the mole ought not to be disturbed, nor is it at all unlikely that many a mole-catcher receives his fee for destroying a mole in a situation where its labours are far more useful than his own. Some of those mole-catchers are very expert in their business, and capture a vast number in the course of the season. Mr. Bell, in his work on British Quadrupeds, now in course of publication, in a very clever article on the mole, gives an account of the success of some of those mole-catchers. He mentions, among others, a Mr. Jackson, who seems to have paid more attention to the economy of his game than most persons of his craft, who for five-and-thirty years has been destroying them at the rate of about twelve hundred a year. It appears from the accounts given by Jackson that the moles make provision for obtaining a supply of water without the necessity of any surface travelling. If there is a pond, a ditch, or any other permanent supply of water within a moderate distance of the feeding grounds,

they open a passage to it, with branches, so that each of the colony may reach it by turns, without any chance of collision with his neighbours. The same authority mentions that, if such a supply of water is not accessible, the moles dig wells in various parts of their runs, and carry them to such a depth as that they can command a permanent supply of water at the bottom. Le Court, who has been already alluded to, was perhaps, however, the most successful of all mole-catchers that ever embarked in the profession; for, though his labours did not extend over a very great breadth of country, he contrived, for five months running, to catch at the rate of twelve hundred moles in the month. He caught them at all seasons and under all circumstances; and sometimes he caught the female mole when in season, and found the attachment of the male so strong that it was literally starved to death beside the trap; nor was he less successful in training others to the capture of these animals, so that, though we are greatly indebted to him for information on the subject of moles, the moles themselves, as a race, are under no very particular obligations to him. He had studied the subject so long and so intimately, that he knew at once, from the aspect of the ground, and the sound which it emitted when struck by a hoe or mole spade, whether there was or was not a mole-run under it. He also knew the time at which to place his traps so as to make sure of his victims, and seldom failed in any one attempt.

The mole-traps used by Le Court were not of the same form as those which are chiefly made use of by mole-catchers in this country. With us the mole-trap is but a clumsy instrument. It consists of a little wooden cylinder, or frequently of a simple bit of board, with two grooved hoops applied to the under side. This instrument is let into the ground, so that the opening of the cylinder or of the hoops answers to part of the mole's run; and in either case there are placed two gins or nooses, which lie in grooves of the cylinder or the hoops, and are connected with a piece of stick outside on the surface of the ground, which answers the purpose of a spring. When free to act, this spring draws the nooses tight enough against the upper part of the cylinder, or against the board, for holding a mole in confinement in spite of its utmost effort to get free; and to prevent this from taking place there is a peg on the under side, which confines the end of a bit of string, and so prevents the stick from pulling the gins until this peg is removed. This peg is so placed as that the mole shall strike it with the greatest lever power, and drive it from its place; and while, when he "comes thundering on," in his career to rest or to feed, he loosens and drives out the peg, he as invariably fastens himself beyond a mole's means of extrication. Clumsy mole-catchers, in their zeal to make the spring of the trap strong enough for catching powerful moles, sometimes contrive to make it catch only itself; and at other times they place it in so bungling a manner that the mole easily gets his snout under it and bores it out of the ground, and, if moles are capable of laughing on such occasions, laughs in his sleeve at the bungling conduct of his intended destroyers. We know not whether this may at any time happen to the regular and more celebrated professors of the mole-catching art; but as one passes over grounds where mole-traps have been set with industry, if not with skill, it is no uncommon sight to observe half

the traps dangling at the tops of the released springs, with not a mole in one of them.

Le Court's traps were of a construction somewhat different, and contained the springs on the under side, so that they could not be jerked out of the ground. The springs were of steel, so formed that when free to act they crossed each other with considerable force, and held the mole against the board to which they were attached. When set, those springs were kept apart by means of a lozenge-shaped piece of iron, the two points of which bore against the insides of the springs, but which was so slightly held in its place that a mole could not strike against it without instantly displacing it, and as certainly being secured with the springs. Mr. Bell mentions that the mole-catchers of this country have made some improvement in this species of instrument; but in much-frequented runs he deprecates the use of a box trap for catching moles alive, because, when more than one get into such a trap, they kill and devour each other. If the simple destruction of moles were the only object in this case, this cannibalism would be of no consequence; but of course the mole-catcher is paid in proportion to the number which he produces. We know not what vestige the victor mole may leave of the vanquished one after the feast of skulls is finished; but very probably they cannot be much worse than the famed cannibal cats of Kilkenny, which left the "two tails and a bit of claw" as evidence that there had been more than one at the fight and the feast. If this is the case, we think the fact of the moles eating or not eating each other is one of very minor importance; because, if the brush is evidence that a fox has been killed, the tail ought to be equally good evidence in the case of a mole.

We must, however, leave the general description of these animals, interesting though they are, and very briefly notice the two species, than which we are not aware that any others are found in any part of the world. It is true that those describers who are fond of multiplying species have contrived to manufacture several out of the common mole, because that animal is subject to considerable variations of colour. Some are found perfect albinos or white all over, others are found yellow; some are found ash-coloured, and some spotted or mottled with different colours. We have not, however, the slightest evidence that any one of these is a species, or even a permanent variety capable of transmitting any one of its variations of colour to its posterity even in one generation. In breaking up lea in some parts of the country, especially when it is done with a deep furrow and the ground friable, moles are often turned up in considerable numbers, both in the mature and the young state; and, though we never saw one perfectly white, we have seen them of a pale ashen colour, interspersed with others of the usual dark hue. Those deep ploughings of their grounds, which destroy camp and highway and castle, are of course sad catastrophes to the poor moles, worse in all probability than earthquakes to human beings; and though, in the moment of their disturbance, they would bite, and bite keenly, they very speedily perish after their exposure to the air. From this obvious blending of the different colours in the same locality there is no reason to doubt that they are all the same identical species, and that there is really no mole in Europe except the two species to which we have alluded. As little does it appear that there are any other species of

true mole in any part of the world; for the golden mole of the Cape, the musk rat of Russia, the star-nosed mole of North America, and various other allied genera, some of which have occasionally been called moles, differ in more respects than mere specific ones from the moles properly so called. We shall therefore restrict them to the two species to which we have alluded, and of which we shall now give a very brief notice.

COMMON MOLE (*Talpa vulgaris*). This animal is so common in most parts of the country as scarcely to require any particular description. It is known by various names in different districts. "Mole," which is its common modern English name, is obviously a contraction of the older one, which is not an unusual way of changing names. The old English name is "mouldiwarp," or "mouldwarp," which simply means that which turns or casts up the mould or soil. In different places the pronunciation is different. In many parts of Scotland it is the "moudiwort," in others the "moudiwark," and in others again it is simply the "moudie." All these are, however, the same word, differently pronounced or contracted, and they all have the same meaning. The intermediate authors sometimes call it "moule," and that as well as "mole" are simple allusions to its working in the mould or earth. We also call an embankment of earth a "mole;" and the word "mall," which is applied to a walk cast up or elevated above the mean surface so as to be dry, is still the same original word. In those parts of the midland counties, especially along the slow-flowing rivers which discharge their waters into the Humber or the Wash, there is a process for the improvement of land which is still called "warping;" and though it is really a deposition of mud, and not a casting of it up, it is also derived from the same Anglo-Saxon verb "*Weorpan*," "to turn or cast up." This process consists in allowing the tide or flood, or both together, when loaded with matter which is known to be useful to land, to flow over the low grounds, and remain there till it deposits its load, after which the water is allowed to drain off, and this produces a new surface soil, bearing some slight resemblance to what would be obtained by the spreading of mole-hills. These etymologies show the attention that the common mole attracted even in comparatively early times. The whole length of the common mole is nearly eight inches, the head being about an inch and seven lines, the body three inches and seven lines, and the tail one inch and two lines. The teeth are six incisors above and eight below, all of equal length. Two canines in each jaw; eight false molars above and six below, and six true molars with tuberculated insectivorous crowns, making in all twenty-two teeth in each jaw, and of course forty-four in the whole. The body is thick and massy for the size of the animal, and of an oblong form, with very little distinction of neck, in consequence of the advanced position of the shoulder joints, to which we have already alluded. From the shortness of the legs, and the peculiarity of their articulation, the whole under part of the animal may be said habitually to touch the ground; and the edges of the fore paws, that is, the inner edges, the very opposite of what takes place in the sloths and anteaters, are applied to the surface. The head, though thick and strong towards the neck, tapers gradually towards the muzzle; and that organ has a great deal of

muscular power as a digging instrument, and not a little as a prehensile one. The eyes are exceedingly small; and even when the animal has occasion to use them, their lids open but a little way, though the eyes themselves are bright and shining. All the teeth are remarkably sharp, and more especially the canines, by means of which, though the mole does not kill its prey in the business-like manner of the true carnivora, it very speedily tears open those animals which it masters while yet alive, and devours their vitals ere they have ceased to feel pain. The incisive teeth are small, but bite very keenly, and the false grinders are shaped like the canines, only much smaller, and they use these in tearing. The true grinders are broad, and have many tuberculous prominences for dividing the food; but there is no proper grinding motion in the jaws. The fore feet are accordingly stout, and formed and used in the manner already explained, the carpus being wholly, the metacarpus partially concealed under the fur. This fur is very short, delicate, and silky, and being inserted perpendicularly in the skin, and not sloping in one direction more than in another, it is not ruffled by any action of the animal against the earth through which it works. The colour may, generally speaking, be said to be deep black; but it is so far iridescent that it shows different colours. If seen from the side toward which it is bent, it is velvet black without any reflections, whereas, if seen from that toward which it is bent, it is glistening grey. In different lights it shows various shades of colour intermediate between those two extremes; and though it does not under any circumstances display the brilliant lustres of the golden mole of the Cape, the whole of its hair has metallic glosses. The tail of the mole is scaly, but the scales are interspersed with longer and stiffer hairs than those on any other part of it, with the exception of the whiskers. The skin of the mole is an exceedingly delicate and beautiful fur, and by no means without durability; but the individual skin is small, and it is not easy to procure a sufficient number for any other than trifling articles.

The *Blind Mole* (*Talpa cæca*). In its general habits, this animal does not appear to differ much from the common mole, though, as we have already said, it is but rarely seen, and altogether an exceedingly obscure animal in its habits. So far as we know, it has never been met with to the northward of the Alps, or indeed almost anywhere but in the Apennines, though there is no doubt that it is the mole described by Aristotle.

Their distinctions are structural, however, and, as such, they are sufficient to warrant us in regarding it as a different species. It is probable that it may be found in other parts of Europe besides those in which it has hitherto been actually found, because it does not appear that there is any circumstance connected with it which necessarily confines it to climates warmer than those inhabited by the common mole; and this is rendered the more likely by the fact of its being found among the mountains rather than in the low countries. It is smaller than the common mole, being about a fifth part shorter from the muzzle to the tail, and its snout is more flattened in proportion. Its colours and general aspect are, however, so like those of the common mole, that a casual observer can distinguish but little difference between them. The characteristic differences are in the incisive teeth and the eyes. In the common mole these teeth are

all of equal length, whereas the blind mole invariably has the two middle ones longer than any of the rest. The eyes of the common mole are small, and the eyelids open only as a little slit; but the eyes of this one, though supplied in nearly the same manner as those of the other, are little else than rudimental; and, instead of being a slit, the opening of the eye is like a mere pin-hole, through which the eye cannot be observed without the most careful examination. But even this circumstance does not warrant the conclusion that this mole is absolutely blind, because we are unable to tell what is the minimum size aperture through which an animal can see. We want farther information respecting the economy of this species, and the points in which it differs from the common mole; and, indeed, the habits of both moles are so different from those of most other mammalia, that few subjects better deserve attention from the observers of nature.

MOLE-CRICKET (*Gryllotalpa vulgaris*, Fabricius; *Gryllus gryllotalpa*, Linnæus).—The very expressive English name of an insect belonging to the family of the crickets (*Achetidae*), but having the burrowing habits of the mole, its fore legs being very similar in general form to the fore feet of that quadruped. We have already, in the article **CRICKET**, given a general account of the habits of this insect; but a few additional particulars from more recently published works will not be thought out of place in mentioning the insect in its alphabetical situation. Unlike the majority of the crickets and *Gryllidae*, the female mole-cricket is unprovided with an exerted ovipositor, so that it is difficult, on inspecting the abdomen of a specimen, to ascertain to which sex it belongs, the same number of segments being found both in the male and female. The wing-covers, however, furnish more certain proofs, the disc in the male being more closely reticulated with nervures; there are also one or two cells at the base, which are, moreover, larger in the males than in the opposite sex. It is a curious circumstance also that a genus so extraordinarily formed as this is should be distributed nearly over the entire surface of the globe. The species are but few in number, but widely extended. The common mole-cricket is exclusive to Europe; there are several American species; Africa and Asia are also inhabited by them; and there are at least two found in New Holland. It still remains to be proved whether the north of Africa possesses the common European species, a peculiarity in geographical entomology

Gryllotalpa vulgaris.

exhibited by various other insects. They seem to prefer cultivated spots, such as kitchen gardens, corn fields, &c., digging a deep cell in the earth, to which they retire during the winter, and which communi-

cates with the surface by a vertical gallery, from whence it excavates various other passages. That they are very destructive to vegetation where they take up their abode is certain, although it is a matter of dispute whether it be by feeding upon the roots, or merely by burrowing round them, that this injury is produced. M. Feburier, who has paid much attention to these insects, and has published a long account of them in the *Nouveau Cours d'Agriculture*, vol. v., p. 163, gives the following reasons for believing that the insect is carnivorous:—Its galleries are more numerous in places where the ground contains the fewest insects, which of course it is compelled to hunt after more extensively; and in gardens where the vegetables are planted in regular rows, and in which the weeds are carefully extracted, the galleries of the mole-cricket do not run from plant to plant, but pass indiscriminately at the sides of the plant or over its roots, destroying them only where they happen to be very tender, and to lie in its way. Moreover, if the beds be manured in the neighbourhood of the mole-crickets, they soon make their way to the manure, especially if it be cow-dung, although there be no trace of vegetable to be seen in it. It has indeed been said that this proceeding had for its object the deposition of its eggs in a situation where, subjected to greater heat, they would hatch the more quickly; but on the other hand it is certain, that they prefer hard ground for the reception of their nests, and that, if the beds are not hard enough, they will burrow into the paths; hence M. Feburier concludes that it is only for the pursuit of the insects which frequent the manure that they approach it. Having placed several individuals together, one of them was devoured by the rest; and the structure of the mouth seems also to indicate carnivorous habits. Mr. Gould also fed a mole-cricket for several months on ants. On the other hand, from some observations published in the second number of the *Revue Agricole*, we learn that dahlias and some other plants have been ascertained to be attacked by these mole-crickets at the roots, and not only perforated, so as to allow a passage to the insect, but the interior of the stems also consumed to a considerable height, and the plant entirely cut asunder. M. Turpen, also, having placed three mole-crickets in a box of earth with a leaf, during the day they buried themselves, but on opening the box at night they were found occupied in devouring the leaf, and the same was observed the two next nights; but on the fourth the largest individual killed and devoured the other two; hence it is beyond a doubt, that the mole-cricket is both herbivorous and carnivorous, and that we have good reason for attributing to it at least a great proportion of the mischief which is laid to its charge. The situation where they reside may be known not only by the yellow and languid appearance of the vegetables, as well as by the little elevated ridge of mould which they cast up like the field-mouse rather than the mole, in the immediate neighbourhood of their central burrow. Various plans have been suggested for their destruction, but they seem to be quite impracticable to any extent, especially as the reproductive powers of the insect are very great. It must, however, be regarded as a rare insect in this country.

MOLORCHUS (Fabricius). A genus of coleopterous insects, belonging to the section *Tetramera*, and sub-section *Longicornes*, having the elytra very

short like those of a *Staphylinus*, and considered by Latreille and some other authors as synonymous with the Linnæan genus *Necydalis*, which see.

MOMORDICA (Linnæus). A genus of climbing plants, natives chiefly of India. They are mostly annuals, and belong to *Cucurbitaceæ*. The *M. elaterium*, or squirting cucumber, belongs to this genus, and is found in the south of Europe; none of them are cultivated.

MONEYWORT is the *Lysimachia nummularia* of Linnæus, a handsome British creeping herbaceous plant found in damp meadows, and sometimes cultivated as an ornamental plant.

MONKEY. The general English name of by far the greater number of the quadrumana, or handed animals, whether we regard number of species, number of individuals in a species, or differences of form. With the APES and BABOONS, notices of which will be found under their respective names in the alphabetical order, the monkeys, in their various families, comprehend the whole of the four-handed animals properly so called; for, though the *Jemurs*, the *Loris*, the *Galago*, and the *Tarrier*, and even *Aye-Aye*, which belongs to a totally distinct order, are in some respects handed animals, they are quite distinct from the true quadrumana in their food and in many of their habits. Under the article **ATRELS** there will be found an account of one group of the American monkeys, namely, the spider-monkey, and those allied to it, which are remarkable for the vast production of their extremities, their slenderness, the awkwardness of their motion upon the ground, and their extreme agility upon trees. In the article **MAMMALIA**, more especially in the department of it which relates to organs of climbing, there will be found some remarks on the general analogies of the different groups; and we shall devote this article to what remain of the monkeys in addition to the explanations formerly given, as by this means we shall save space, and, described in juxtaposition, both the agreements and the differences of the several families will be more clearly understood than if they were described, even at greater length, in articles widely separated from each other by the alphabetical arrangement.

Monkeys of all families are forest animals, generally living in trees, among the branches and twigs of which they make their way with very extraordinary celerity. Much of the food of the whole of them is vegetable, consisting not of leaves, but of fruits, succulent or farinaceous, with which the forests of tropical countries abound; but there are few, and perhaps none, which do not add insects to their vegetable food; and so fond are they of this addition, that they may often be found hunting for insects in the fur of each other in a manner which but ill accords with our notions of cleanliness.

Formed for a particular purpose in nature, namely, that of getting from branch to branch of trees with the greatest expedition and ease, the whole of them are what we would call unshapely animals. The position of their eyes, which are directed forwards in all the species, and the rude resemblance which their faces have to human beings, together with the hands, which, though most unlike the human hands, are still grasping instruments, further increase the repulsive feeling which we have in looking upon them. No man likes to be caricatured; and as the monkeys are vulgarly considered as a sort of general caricatures of the whole human race, their appearance

is repulsive to every body. This repulsiveness of appearance is, however, somewhat redeemed by their extreme agility; and on this account, though monkeys are in some instances very mischievous and very ugly animals, they are attractive in a menagerie, especially to the young; and, where extensive collections of live animals are kept, a crowd will be generally found in front of the dens or cages containing the monkeys. The true apes are animals of more grave character; and the baboons are exceedingly repulsive in their appearance, and offensive in many of their habits, as well as exceedingly ferocious in their dispositions; so that the monkeys are the only division of the quadrumana which can be looked upon with anything like satisfaction. This satisfaction is not produced by their appearance, but by their actions, their lively motions, their mischievous tricks, and, in minds of more tender cast, by the extreme attachment which the mothers have for their young, and, indeed, all the individuals of any one species for the other. When exhibited in our comparatively cold climate (for our temperate weather is more rigorous than the depth of winter to those children of the tropical forests), the efforts of two monkeys to keep each other warm, by each clasping round the body of the other, and the still greater efforts which a male and female make to keep a young one warm between them, are among the prettiest displays of animal solicitude with which we are acquainted.

There is of course none of what we are in the habit of calling kindness—that is, kindness from a forethought purpose, and with the intention of producing a specific effect, of which a knowledge has been obtained by experience, in any part of the conduct of monkeys, any more than in that of other creatures not endowed with reason; but still the act of an irrational animal tells upon our feelings, very much in the same way as if it were the act of a rational one; and therefore we feel a sympathetic pleasure in the apparent kindness of such an animal, very nearly allied to what we would feel in the case of that which we consider an analogous action performed by one of our own species. This is no doubt a mistake in the philosophy of the case; but it is a mistake on the part of kindness; and it is not only a confession on our part of the delightfulness of tender conduct, but it strongly induces us to be tender of the animals themselves; and thus, by our sympathy with those irrational creatures, we, without perhaps knowing it, make them the means of kindheartedness in ourselves, which is one of the most valuable results that we can obtain from the study of animals.

The active means which these little creatures (for they are, generally speaking, little in volume of their bodies, though large in the lineal dimensions,) must employ in the finding of their food, and the danger to which their young are exposed from more powerful animals, render it necessary that the females should be able to carry the young along with them in their rapid movements among the branches. For this purpose both mother and young are beautifully adapted. The pectoral part of the body of every monkey is by far the most muscular and robust in its form, while the ventral and sacral parts of the trunk are attenuated, so much so that this portion appears, in some of the species, as if it were nothing more than a stalk to the hind legs; at all events it is never such as to impede their motions or encumber them by its weight. Now the young monkey so applies

itself to the body of its mother as that it in no way impedes her motions, and is, in fact, the least possible burden to her that so much additional weight could be. The clavicles are stout and long for her size, by which means the breadth of the chest is ample, and the shoulder joints are thrown wide apart. The fore legs of the young clasp her round the neck, or at all events the hands upon these hold on the immovable part of the shoulder, between the clavicle and the blade-bone, so that their points of adhesion do not interfere with any of the moving parts. These members in the young one are so long that it can reach the pectoral mammae of the mother without weakening its own hold or cramping her motions; and then its hind legs clasp the body so far forwards, that they leave the posterior extremities free for every operation of climbing. Therefore a female monkey, loaded with a young one, has very nearly, if not altogether, the same use of her organs of motion as though she were without any load, because the young one adheres by its own exertion, which exertion strengthens in proportion to its weight. This is not confined to the monkey tribe, but extends to all those tree mammalia which carry their young along with them as they climb in search of their food. Such mammalia have seldom more than two at a birth; and it is highly probable that nature endows them with additional strength to compensate for the labour of carrying their young ones, and the exhaustion of suckling them. The way in which nature adapts the capabilities of females to the necessities which their functions in the economy of nature require, is both a curious and a beautiful portion of physiology, and it deserves to be studied with far more attention than it has hitherto met with. Common observation tells us that, if the safety of the young required, the degree of strength or courage, or both, with which the female can be endowed for the occasion, is not to be estimated by any ordinary comparison between her and the male. A common hen, when she has no brood, is one of the most feeble and timid of creatures; but give her once a following of chickens to gather under her wings when they are cold or wearied, and the eagle herself has not more daring. She can not only set the raven and the kite at defiance, but will at once fly in the face of a dog or fox with such determination as to send them speedily to their retreat.

Now, in the same manner as this mother is furnished with the means of protecting her offspring in their helpless state, we may naturally suppose that every other mother will be strengthened for the time according to the necessities which that time involves; and that among others, the female monkey will be endowed with additional strength and energy, in order to enable her to carry the burden of her young one, and at the same time procure the additional supply of food which the drain occasioned by that young one renders necessary.

There is no monkey found native in any temperate climate; neither is there any which is perfectly at home and in full vigour when carried to such a climate. It is true that monkeys are more hardy than apes properly so called, and perhaps even than baboons, though the repulsive appearance and offensive manners of these last hold out little inducement for making experiments upon them; but still even in our climates, and protected in buildings, if these buildings are not artificially warmed, they suffer severely in the winters of the mildest districts of England, and can-

not at all exist in climates which are much colder. This is not very seriously to be regretted; for, notwithstanding all the liveliness of their tricks, monkeys are ugly and mischievous creatures, and perhaps none are more offensive, except those human beings who, in common parlance, are described as making certain remarkable approximations to the monkey. On this part of the subject there is something very curious, and which, very probably, would furnish curious information if our limits and our purpose would admit of our working it out. It is this: whenever a human being seeks to entertain an audience, or otherwise to amuse his fellows, not by mental wit, or any other accompaniment which belongs to man as man, but by harlequinade, buffoonery, or any thing else belonging to the category of what are usually termed monkey tricks, if his visage and person are not naturally distorted and deformed, so as to deviate as far from the proper type of man as possible, then he must make out his deformity by piebald clothing, and padding and paint, and wriggle his limbs into flexures as inhuman as those of a spider-monkey; nor must it be concealed that since theatrical exhibition fell from its high and intellectual state, and sunk to the tom-foolery of the rabble, an ugly face is a surer passport to fortune than the highest intellect that ever graced a classical stage. It is in some such fashion as this that the study of the monkeys at once schools us in the foibles of our own species, and chastises us for the practising of them.

In the wild woods of the Oriental Islands, of tropical Africa, or of America, the monkey is in its place, and it is a beautiful specimen of that perfect adaptation which runs through the whole system of nature; and it would certainly take nothing from the wisdom—and, *ceteris*, very little from the real mirth of society, if the real monkeys would kennel with their kindred of the woods. *De gustibus non disputandum est*, and, if any of the *Bimana* will prefer monkey to man, we have no right to quarrel with his election.

In the tropical forests the different genera of monkeys are exceedingly numerous and highly characteristic. They are rarely if ever found in open countries, as neither their food nor their organisation fits them for finding their subsistence upon the ground. Accordingly, they are found in patches, of which patches there are three principal ones, and the monkeys of each are so distinct from those of the others, that it may with truth be said, that not a single species is a common inhabitant of two.

The three patches of the globe, or monkey lands to which we have alluded, are the south-east of Asia and the adjacent isles, the west and south of Africa (though some compilers, Sir William Jardine among the rest, in his *Naturalist's Library*, plants them on the east of Africa, and fetches Guinea there for their accommodation)*, and the tropical forests of America. In all of these districts the monkeys differ in appearance from those of the others; though they agree so much in their habits and the essential parts of their organisation, that the generic differences do not follow the geographical ones, unless between the monkeys of the eastern and the western continents.

But, notwithstanding the interest which this family

of animals has excited; and the quantity of description which has been published concerning them, their natural history is still in a very confused and imperfect state. One cause of this is the extreme difficulty of exploring the haunts of many of them; another is the delicacy of the Oriental ones, which cannot bear even the temperature at sea, or the passage round the Cape, and of course are rarely brought alive to Europe; and a third is the avidity with which animals and the skins of animals used to be bought up for the purpose of increasing the raree-show attractions of museums, without any inquiry respecting the native locality of the animal, or its habits in that locality, which are not only the most important, but almost the only important parts of the whole matter. At this day there are more species of monkeys in European museums than have been actually discovered in a living state in any part of the world; and this circumstance alone throws a great deal of uncertainty into the whole natural history of the race. From distinctions which we shall afterwards notice, it is very easy to decide whether any monkey is a native of the eastern continent or of America. The African and the Asiatic species also, as observed in the two countries, generally speaking, differ from each other; but it was for a long time difficult to ascertain whether skins and specimens of dead animals were Asiatic or African, because the two were blended together in the general market at the Cape, and the sellers cared little or nothing for the country of the specimen, so that they obtained their price for it. The researches which have been recently carried on in the natural history of India by British officers on the different stations, now that India is at peace, and especially those carried on in Java by the example and under the patronage of Sir Stamford Raffles, have thrown much light upon the natural history of that highly interesting portion of the world; and those labours have gone a considerable way in deciding what species of monkeys of the eastern continent are Asiatic, and what are not.

We shall not take the strictly systematic arrangement of monkeys according to their genera, because some of these are not very distinct. There are some differences in the structure of the teeth, which indicate corresponding differences in the food and disposition of the animal. Some, for instance, have the canines strong and a good deal produced, and the cheek-teeth with tuberculated or insectivorous crowns, while others possess these characters in a much lower degree. There is none of them, however, which can be considered as absolutely of a carnivorous character; and there is none which can be regarded as having the mouth exclusively adapted for vegetable feeding, though the greater part subsist chiefly upon vegetables. We shall take our principal division according to the geography—noticing first the monkeys of the eastern continent, and then those of the western, the former being intermediate between the latter and the apes and baboons; and we shall add such generic names as are usually given by others.

I. MONKEYS OF THE EASTERN CONTINENT.—Most species of these are exceedingly numerous, and they are very agile in their motions. Their tails are often long, but they are not prehensile.

The *Red Monkey* (*Cercopithecus ruber*) is one of the species which has been longest known. The characters of the division to which it belongs are:—

R

* It (the Diana monkey) is a native of the eastern coast of Africa, principally in Guinea, is about eighteen inches in length, with the tail exceeding two feet.—*Nat. Lib., Man.*, vol. 1, p. 132.

the facial angle about fifty degrees ; the head rounded ; no projecting ridges at the eyebrows, but the margins of the orbits smooth ; the nose flat, with the nostrils opening in nasal grooves ; the ears of moderate dimensions ; the mouth furnished with cheek-pouches, external of the teeth ; the buttocks with naked callosities, and the tail longer than the body. The red monkey is an African, found in Senegal, where it inhabits the woods, and is a very active little animal. Its body is about sixteen or seventeen inches long, and its tail nearly the same. The upper parts are not red, but of a reddish-fawn colour, very bright. This colour passes into greyish on the limbs, and the face, the cheeks, and all the middle of the under part are pure white. The face is peculiarly marked, there being a black band over the eyes, which has the appearance of eyebrows, and two black bands on the lips, which resemble mustaches. The hair of these is not, however, more produced than the differently coloured hair by which it is surrounded. This is one of the species which has been longest known, and it is mentioned by the earliest of modern naturalists. It is an active species, and very lively, dancing about in a very peculiar manner when in a state of confinement ; but it is exceedingly irritable, and liable to do mischief if tampered with. It has been frequently brought to this country, and, like the rest of the genus, its form, though by no means symmetrical for a walking animal, is rather more handsome than some of the other monkeys. The nature of the country which it inhabits, in which there are detached trees rather than close forests, requires that it should be better able to walk than many of the others ; but still its walk, although tolerably rapid, is leaping and inelegant. Contrary to the structure of the apes, its hind legs are longer than its fore ones ; and its hind feet are particularly long, and so articulated, that it can either apply the whole tarsus to the ground, or only the metatarsus ; and when it does the latter, it possesses the same number of joints in the leg as those animals which are properly digitigrade. The fore feet are always plantigrade in the monkey tribes, the carpus being very short as compared with the tarsus.

The Varied Monkey (Cercopithecus mona). In a race of animals not very remarkable for their beauty, this has often been described as surpassing all the others in that respect ; and the markings of its colours are certainly very striking. The native country of this monkey has not been very satisfactorily made out, or at all events there are some disputes about it. It is African, and is understood to be a mountaineer, and to inhabit the mountains of Atlas, though we are not aware that any European has hitherto observed it in those mountains. Its manners in a state of nature, and the fact as to whether it is more a tree or a ground animal, have not been satisfactorily ascertained. From the specimens which have been kept in confinement, it appears, however, to be more hardy than almost any other of the monkeys ; and it is also susceptible of a good deal of education. It is an animal of great cunning and resource, and is perhaps the most expert pickpocket of all the four-handed race. It can open locks by turning the key ; empty a pocket so gently as that the owner cannot perceive it. It can also play a number of other tricks, and it is more sensible to kindness than any other monkey. There is also nothing particularly offensive in its habits ; and, as its colours are singularly contrasted,

it is one of the very few which can be kept in captivity without exciting any repulsive feeling. The following is a description, by Mr. Bennet, of a specimen in the gardens of the Zoological Society of London :—"The top of the head is of a greenish-yellow, mingled with a slight tinge of black ; and the neck, back, and sides, are of a deep chestnut-brown, passing downwards as far as the shoulders and haunches, where it changes into a dusky slate colour, which is continued on the limbs and tail. The latter organ is considerably longer than the body, and has, on each side of its base, a very remarkable white spot. The under surface of the body and the inside of the limbs are of a pure and delicate white, separated from the neighbouring colours by an abrupt line of demarcation.

"The naked upper part of the face, comprehending the orbits and the cheeks, is of a bluish purple ; the lips, and so much of the chin as is without hair, flesh-coloured ; on the sides of the face, large bushy whiskers of a light straw colour, mixed with a few blackish rings, advance forwards and cover a considerable portion of the cheeks. Above the eyebrows is a transverse black band, extending on each side as far as the ears, and surmounted by a narrow crescent-shaped stripe of grey, which is sometimes scarcely visible. The ears and the hands are of a livid flesh colour."

The Diana or Palatine Monkey (Cercopithecus Diana). This species was named Diana by Linnæus in consequence of the slight resemblance which a white spot on its forehead has to a crescent which was the emblem of the fabulous divinity, whom the ancients made the patroness of hunters. This species resembles the two former in its shape, and, like them, it is an African ; but it inhabits nearer the equator, and is chiefly found in the woods. The length of its head and body is about a foot and a half, and that of its tail about two feet. Its general colour is a mixture of black and white on the upper part, passing gradually into ash colour on the head, neck, and lower part of the body. On the middle of the back the black predominates, and so it does also in the tail, the tip of which is entirely black. The crescent of white above the eyes, the points of which extend nearly as far as the ears, is its most remarkable feature, and the one by which it can be distinguished from every other monkey. This species has been frequently brought to Europe ; and though, from being a native of very tropical countries, it feels a great uneasiness during our winter months ; yet if it is kept warm enough it will live in our climate. It feeds chiefly upon vegetables, of which it prefers nuts and sweet fruits ; but it also eats bread, and even eggs, though it does not eat flesh, or attempt to kill any warm-blooded animal for the purpose of eating it. It is, however, an ill-natured and snarling animal, always showing its teeth when a stranger approaches it, and biting severely if it can get within reach. It seems that, in a state of nature, it procures great part of its food by the scent ; for, when confined, it smells very carefully at every object, and at the same time turns it round to examine it ; so that, if food is given to it in a dish, the first thing that it does is to turn the dish upside down. It drinks a great deal ; and, for its size, its appetite may be said to be voracious. The fact of this monkey eating eggs when in a state of confinement would lead one to suppose that the eggs of tree birds form at least a part of the

food of some of the tree monkeys. Indeed, without having recourse to some such food as this, it is not easy to suppose how the countless multitudes of them which swarm in the tropical forests could by possibility exist.

There are many other species of monkeys included in the genus *Cercopithecus*, as established by the systematists; but some of them are doubtful, because we do not know the changes of colour, or even of shape, that these animals may undergo at different ages. It is ascertained, in the case of some which have longer muzzles than those of this genus in the adult state, that they have them comparatively shorter when young; and it is possible that these young ones may have been erected into species, as has often been done with the young of other animals. We shall, therefore, only mention the names of the principal ones, with their localities as far as these are known, for their manners differ but little.

The Golden Monkey (C. auratus) is golden yellow on the upper part, and pale lemon yellow or whitish on the under. It has the hair on the sides of the head and on the breast very long, and each knee is marked by a black spot. It is understood to inhabit the south-east of Asia, both the main land and the islands.

Mustache Monkey (C. cephus) is an African, of a greenish-brown colour, with the distal half of the tail red, and the nose and lips bright blue.

The White-nosed Monkey (C. nictitans) is an inhabitant of the forests of Guinea, and has the nose and the lower part of the chin white, the former being generally a good deal produced. On the other parts it is blackish mixed with grey, and passing into lighter on the belly.

Vaulting Monkey (C. petawista). This one is also an African, and gets its name from the height which it can leap from the ground, and also the distance from branch to branch. Its colour on the upper part is reddish, passing into white, and the point of the nose is also white. The outsides of the legs have a greenish tinge, and the insides are grey.

The Grey Monkey (C. albocinctus) is a native of the Oriental islands. As its name implies, its general colour is whitish ash; being grey above, with the outsides of the legs of a darker grey, and whitish below. The tail is brown; and a ridge of hairs on the forehead, and also the naked skin on the feet, black.

Red-breasted Monkey (C. pygerythrus) is a native of Southern Africa. Greenish-grey on the upper part, whitish on the under, with a black tip to the tail, and red hairs under its insertion.

The talapoin monkey, the purple-faced monkey, the bonneted monkey, and one or two more, have been described as belonging to this genus or subgenus; but they are known only from single specimens, and we are not acquainted with the native locality of any of them.

The monkeys of this genus make the nearest approach to the true apes, being, like them, comparatively short in the muzzle; and thus the generic name, which means "tailed apes," is not inaccurately bestowed. Generally speaking, they are animals of more cunning and resource than the other monkeys; and they are rather more handsome in their appearance, although in that respect even they have not very much to boast of. They are irritable, mischievous, and not to be trusted.

A second genus, or rather perhaps subgenus, of monkeys have received the name of *Semnopithecus*, or venerable apes, from the length of their beards and whiskers, the gravity of their appearance, at least in some of the species, the slowness of their motions, and the length and slenderness of their limbs, which make them look as if they had dwindled to

The lean and slipper'd pantaloon.

This character is not, however, just, as applied to the whole, at least as they are usually arranged; but they differ from the former section in a sufficient number of particulars for warranting their separation from it. Their leading characters are:—a small tubercle on the last molar of the under jaw, which is wanting in the *Sercopithecus*, from which we may conclude that the present section are more herbivorous; their muzzles are rather more elongated, with the head round, and the nose very flat; the ears of moderate length; the limbs very long, with very short thumbs on the fore paws, placed far back from the fingers, thus rendering the paw by no means an efficient instrument for holding any thing between the thumb and fingers; the tails are long and thin; and the cheeks are furnished with pouches, and the buttocks with callosities. The whole of them are inhabitants of the eastern countries; and of course it is exceedingly difficult to bring them to Europe in the living state; and thus, though many of them are abundant in their native regions, and some are even objects of religious worship, it is but recently that they have been well understood by European naturalists.

Entellus Monkey (S. Entellus), though one of the most common and most celebrated in India, has not been long admitted into the European systems. The Zoological Society of London possessed at least one specimen, as well as some of the other species or varieties of this subgenus; but they did not survive long enough for enabling much knowledge to be obtained of their manners in a state of confinement; and though little inference could thence have been drawn respecting their conduct in their native east, yet the peculiar form of their fore-paws, and the additional tubercle upon the lower grinder, would lead one to suppose that they may occasionally make their progress back undermost, after the manner of the sloths, and feed, in part at least, upon green vegetable matter. The specimen which died at the Zoological Gardens, in the early part of the summer of 1833, was described by Mr. Bennet, and dissected by Mr. Owen; and, as those are excellent authorities, we shall quote the description, and briefly allude to the dissection. "When taken at an early age," says Mr. Bennet, "they are readily tamed, become playful and familiar, are extremely agile, although generally calm and circumspect in their motions, and learn to perform a variety of tricks, which they execute with no little cunning and address. After a time, however, their playfulness wears off; their confidence is succeeded by mistrust; their agility settles down into a listless apathy; and, instead of resorting as before to resources of their ingenuity for carrying any particular point, they have recourse to the brute force which they have acquired in its stead. At length they become as mischievous, and sometimes even as dangerous, as any of those monkeys which in their young state offer no such indications of good temper and intelligence. It is of a uniform ash-grey on the

R 2

upper parts, becoming darker on the tail, which is greyish brown, of equal thickness throughout, and terminated by a few long hairs running out into a kind of point, but not forming a tuft. The under surface of the body is of a dingy yellowish-white; and the fore arms, hands, and feet, are of a dusky black. The fingers of both extremities are very long, and the thumbs comparatively short. The face, which is black, with somewhat of a violet tinge, is surmounted above the eyebrows by a line of long stiff blackish hairs, which project forwards and slightly upwards. On the sides of the cheeks, and beneath the chin, it is margined by a beard of greyish white, passing along the line of the jaws, and extending upwards in front of the ears, which are large and prominent, and of the same colour as the face. The hairs of the fore part of the breast appear to diverge from a common centre. The height of our specimen, which was not yet adult, when in a sitting posture, exceeded two feet; and his tail, which he rarely displayed at full length, but more usually kept curled up in a single coil, measured nearly three feet."

The dissection of this specimen of entellus monkey by Mr. Owen, as well as that of another species to be afterwards noticed, and also of some others by foreign comparative anatomists, would lead to the conclusion that monkeys of this division are very distinctly marked as a separate genus, both in their structure and in their food. We have already hinted at the peculiarity of their general appearance, their lengthened limbs, their long and slender tails, their comparatively grave aspect and manners, and the slowness of their motions as compared with the *sercopithec*i; and in their internal structures they differ a good deal more. They are not ruminating animals; for no handed animal ruminates, except by a sort of inexplicable formation or habit in the individual, which species of monstrosity is not unknown even among the human race. The author of this article knows two instances of men who ruminated almost as regularly as cattle. Both of them were labourers, men of large body and remarkably strong, but clumsily made, and very dull in an intellectual point of view. Both could take a vast quantity of food at one time; and one at least could take as much of food that pleased him as kept him ruminating away for two days, or perhaps more. The quantity which he took on these occasions was as much as would have sufficed for one full meal to at least half-a-dozen of ordinary labourers performing each an equal quantity of work. He was much disliked by the other labourers; but whether solely in consequence of this rumination, or from some moral cause, we were then too young for ascertaining, but the facts which we have stated are unquestionable. If he had continuous work for a succession of days, with a regular supply of food (for he always bargained for food as well as wages), he did not eat very much more than ordinary men until Saturday came; and then he was understood to lay in as much as served him during the Sunday, the servants at the farm where he worked having instructions to victual him for that day as a matter of course. If, however, David, for that was his Christian name, came to the last day of a job, and had not another immediately in prospect, "the lion of the north" could not have been more zealous in providing for his army during a campaign, nor the redoubted Dougald Dalgetty more industrious in filling his own magazines, than David was in storing his internal receptacles as a resource

during the days of uncertainty; and it was alleged, though with what truth we know not, that if, duly impressed with the chance of getting no more during the time, he could victual himself for a week.

Now, if such be the case with human beings, in whom the stomach is simple (and we have heard of many instances besides those alluded to), we may naturally conclude that such of the quadrumana as have compound stomachs may be liable to more frequent instances of rumination. In all animals which have cheek-pouches, those pouches may be regarded as to a certain extent answering the purpose of a simple receptacle of food, something analogous in office, though not in situation, to the paunch of the ruminantia; and when we admit this, the *sercopithec*i have really a sort of four stomachs; and it is worthy of remark that the monkeys having this structure are confined to one particular region of the world, namely, the south-east of Asia. The specimen of entellus monkey, dissected by Mr. Owen, measured twenty inches in length from the muzzle to the root of the tail; and the stomach measured thirty-one inches along its convex side, or side of greatest curvature, and twelve inches along its least. Its circumference where widest was thirteen inches, and where narrowest a little less than four. It was pretty distinctly divided into three parts, the first of these forming a simple pouch, not very large, slightly divided into two at its extremity, and smooth and simple in its containing surface: the next and by far the larger portion was sacculated, or formed into a series of purses in the inner surface: and the third was long and narrow, sacculated at the commencement, and becoming smooth towards its union with the intestinal canal. This third division was by far the most vascular, and most abundantly supplied with ramifications of the gastric nerves, from which Mr. Owen concluded, with every appearance of truth, that it is the true digestive stomach, and that the other parts are only receptive and preparatory. In addition to these peculiarities of the stomach, the intestinal canal was found to be much longer in proportion than in the *sercopithec*i, as these again have them much longer than the baboons and monkeys with produced muzzles. The difference in this respect is very remarkable, as the *semnopithec*i have the intestinal canal about one-fourth longer than the *sercopithec*i, and one-half longer than the genus *Macaco*.

This remarkable difference in what may be considered the most important system of organs in these animals, as connecting them most immediately with the rest of nature, and regulating the kind of their food, which again must regulate the places where it is to be sought, and the means of acquiring it, is well worthy the attention of every one who wishes to study these animals with success, as showing that we are not to take the mere possession of prehensile paws, or hands on the extremities, as establishing any thing like an identity of food among the animals. It is also worthy of remark that these comparatively slow-going monkeys, which have the digestive system much more developed than the agile *oues*, stand something in the same relation to them as the larger ruminants do to the more energetic and more simple stomached of the footed animals. This alone would lead us to look upon the *semnopithec*i as making a slight approximation towards the sloths, if not absolutely in their mode of life, at least partially in their feeding. Accordingly, upon comparing their digestive

organs, it is found that there is a very considerable resemblance between them and the sloths, and also between them and the kangaroos, which are ground animals, and quite different in their appearance and their other habits. But though the species of this genus, or, at all events, some of them, are very plentiful, it should seem that their habits in a state of nature are obscure, as compared with those of the more active monkeys; for we know exceedingly little of the conduct of any of the species in the forests.

The entellus is an animal of somewhat singular appearance, of which some idea may be obtained from the annexed cut.

It is generally said that this is the species to which divine honours are paid by the Hindoos; and it is by no means unlikely. Quiescence, and, in some instances, complete and stubborn repose, even in attitudes which are exceedingly painful, as well as unnatural, is the measure of sanctity; and thus the apparent gravity of this animal, its meagre form, and staid and melancholy face, may be good grounds for that adoration which it is said to receive from the Brahmins. The Hindoos not only regard this species with religious veneration, but treat it with the greatest kindness and forbearance, and, in consequence of this, it is exceedingly familiar in the villages of the natives, where it plunders the gardens, and even enters the houses, and helps itself to such fruits as it may find, whether the owners are within or not; and though these are at their meals, and it comes and seizes a large share, they never offer it any violence. It is, in fact, one of the most privileged of animals; and those loathsome insects, for whose accommodation and comfort hospitals are built and endowed, and attendants appointed, at Broach and other places, do not stand higher in the calendar of saintship than the entellus monkey. Though this is a very slow animal in its walking motions, the length of its legs make it a most expert leaper, more so perhaps than any other of the oriental species.

The Negro Monkey (S. maurus). This is the middle-sized black monkey of some authors; but, though it has got the name of the negro monkey, it does not inhabit the country of the negroes, but the eastern isles. Java is the island in which it has been principally observed by Europeans; but there is little doubt that it extends over the other islands. We owe

the only good description of this, as indeed we do of very many of the animals of the oriental isles, to Dr. Horsfield, whose very able description we shall quote, in preference to taking one at second hand, or of making it up with additions from authorities less worthy of credit. "The covering of the negro monkey," says Dr. Horsfield, "in adult subjects, is intensely black on every part, except the breast, the abdomen, the inner side of the extremities, and the root of the tail; these parts are grey. On the crown of the head the black hairs are slightly tipped with grey; and as age advances, the grey portion becomes more extensive, and also shows itself on the upper parts of the body; but the extremities exteriorly, and the tail, even in the oldest subjects, retain their blackness. The hairs are remarkably long, delicate, soft, and silky. On the sides of the head they are disposed backwards with a slight inclination outward, and on the ears completely conical. They rise with a gradual slope on the forehead; but on the crown of the head they are suddenly deflected, so as to form a dependent crest. On the back and the extremities they lie smooth and close. They are greatly elongated on the sides of the body, between the shoulders, so as to hang down to a considerable length when the animal walks on all fours. On the breast anteriorly, and on the abdomen, they are short, lax, and straggling. In its young state it exhibits a great contrast to that in the adult. Immediately after the birth our animal has a fulvous or reddish-yellow colour; as it advances in age, the colour gradually changes. A grey discolouration first shows itself on the hands, the forehead, and the tip of the tail: from these parts it gradually extends to the neck, the shoulders, and the flanks, and assumes from time to time a darker hue, until the coat of the animal is jet black above, and grey underneath. The face is regularly circumscribed by hairs, which are long, and closely applied to the head; the forehead, which is gradually sloping, is entirely concealed by them. The orbits of the eye are rather prominent, and the bones of the nose short. The nose consists of an angular ridge, which is considerably elevated between the eyes, and terminates, without any fleshy protuberance, by a membrane which is gradually attenuated below, and on each side of which the nostrils are placed. These are large, oblong, slightly curved, and pass backwards into the cranium in a horizontal direction. From the termination of the nose to the mouth a considerable space intervenes; but the lips are small and thin, so as to exhibit, when slightly retracted, the interior of the mouth. The chin is short and small; a circle of grey hairs encloses the mouth in the adult animal, and on the chin the hairs have a disposition downwards, so as to exhibit the appearance of a beard. The upper part of the face is nearly naked; a few straggling stiff hairs are scattered on the cheeks and the upper lip, and on the more prominent part of the nose an interrupted series is observed. The irides of the eyes are of a dark brown colour. The ears are concealed from view by the long hairs which cover the lateral parts of the head; they are margined, and both in form and disposition of external parts closely resemble these organs in man. The neck is short and considerably contracted. The trunk is of great length, broad and robust about the shoulders and breast, and gradually of smaller dimensions towards the loins. The buttocks are marked with very large rough callosities. The mammae in the adult female

are lengthened and cylindrical. The tail is as long as the body and head taken together; in some individuals, and particularly in young subjects, it exceeds these parts in length: it is cylindrical during the greater part of its length, the base is gradually tapering, and the tip is thickened and terminated by a close tuft of long hairs, of an ovate form. The *Semnopithecus maurus* is distinguished among the Javanese by the name of budeng, from another species which has the same form and habit, but a different external covering. The name of the latter is lutung; but the Malays and Europeans apply this name to both species, and distinguish them by the epithet of black and red; the budeng being denominated *Lutung hitam*, and the lutung of the Javanese *Lutung mera*. In Sumatra the name of the 'maure' is latong. The budeng, or the black species, is more abundant than the lutung, or the red species; and the latter, both on account of its variety and comparative beauty, is a favourite among the natives. Whenever an individual is obtained, care is taken to domesticate it, and it is treated with kindness and attention. The budeng, on the contrary, is neglected and despised; it requires much patience in any degree to improve the natural sullenness of its temper. In confinement it remains many months grave and morose, and, as it contributes nothing to the amusement of the natives, it is rarely found in villages or about the dwellings. This does not arise from any aversion of the Javanese to the monkey race; the most common species of the island, the *Cercopithecus aygula* of Geoffroy, the *Eget* of Penman, is very generally domesticated, and a favourite custom of the natives is to associate it with the horse. In every stable, from that of a prince to that of a mantry, or chief of a village, one of these monkeys is found; but I never observed the buteng thus distinguished. The *Semnopithecus maurus* is found in abundance in the extensive forests of Java; it forms its dwelling on trees, and associates in numerous societies. Troops, consisting of more than fifty individuals, are often found together. In meeting them in the forests, it is prudent to observe them at a distance. They emit loud screams on the approach of man, and, by the violent bustle and commotion excited by their movements, branches of decaying trees are not unfrequently detached, and precipitated on the spectators. They are often chased by the natives, for the purpose of obtaining their fur. In these pursuits, which are generally ordered and attended by chiefs, the animals are attacked with cudgels and stones, and cruelly destroyed in great numbers. The skins are prepared by a simple process, which the natives have acquired from the Europeans, and they conduct it at present with great skill. It affords a fur of a jet black colour, covered with long silky hairs, which is usually employed both by the natives and Europeans in preparing riding equipages and military decorations. The budeng, during its young state, feeds on tender leaves of plants and trees, and, when adult, on wild fruits of every description, which are found in great abundance in the forests which it inhabits."

There are various other species or varieties of semnopithecus found in the oriental Archipelago, the best accounts of which we have from Sir Stamford Raffles, Dr. Horsfield, and the two French naturalists, Diard and Duvancel, who co-operated with the English governor of Java and his fellow-labourers in exploring the natural history of these remarkable islands. We

must confine ourselves to very brief notices of these animals.

The *Simpai Monkey* (*S. melolophos*). This species is found in the oriental Archipelago, and also in the southern parts of the Malay peninsula, on the opposite side of the Straits of Malacca. The head and body are about one foot six inches long, of which the head occupies four inches; the tail two feet eight inches; the height at the shoulder, when standing on all fours, thirteen inches; and the height at the crupper sixteen inches. The face of the simpai is very flat, giving it an apparent development of cranium which would lead those who apply the canons of phrenology to the monkey race, and gauge intellect of all kinds by the forms of bones, to impute to it a very high degree of intellect. Those who have seen it in its native localities, however, do not speak of it as possessing more sagacity than the rest of its tribe, which, though, generally speaking, active and mischievous enough, are not remarkable for the possession of any one useful or estimable quality. The colour of this species is bright red on the upper part of the body, with the hair on the sides of the face, the outsides of the legs and tail yellowish; the breast and belly are whitish; the hair on the cheeks is directed forwards; and the head surrounded with a circle of black hairs, and there are long hairs of the same colour on the shoulders; the naked part of the face is blue, with the exception of the upper lip and chin, which are flesh-coloured; and the ears are also blue; the naked skin of the paws and callosities is black; the belly is nearly naked, but the other parts are covered with long and woolly hair, but not very thick. There are seven lumbar vertebrae, and thirty caudal ones. Little or nothing is known of the manners of this animal in a state of nature.

The *Croo Monkey* (*S. comatus*). This species, which is also called the crested monkey, or the mitred monkey, from the length of the hair on the top of its head, is a native of the eastern Archipelago, and was first discovered in Java by M. Diard. It is steel grey on the upper part, the forehead, the upper part of the tail, and the outsides of the legs, and sandy white on the under parts. The paws are differently formed from those of any other of the semnopithecus, the fingers being proportionally much shorter. This difference leads us to infer that there must be a difference also in the habits of the animal; but what this difference is, we know too little of its manners to be able to ascertain. The tuft of black hairs forming the crest or mitre on the top of the head is long; but the hair on the rest of the body is shorter and more glossy than that upon any other of the monkeys, which circumstance would again lead us to infer that it is differently exposed to the atmosphere, and probably that it is to a considerable extent a nocturnal animal.

The *Chingkou Monkey* (*S. pruniosus*). This species is a native of the same countries as those of this division which have been noticed, and, like them, it is but little known. In many respects this species bears a strong resemblance to the croo monkey, and indeed the chief distinction between them is in colour, which is little to be depended on, the more especially as we are ignorant of the changes which these animals may undergo in this respect at different ages, and also of the effects which situations more or less exposed to the elements may have upon them. The general colour of this monkey is black, only there is little

hair on the under part, which gives that a lighter shade; and the blue skin of the upper part shining through the hairs takes off their black appearance. The ears and face are naked, excepting the lips, which are covered with a few white hairs, passing into a sort of tuft at the angles of the mouth. It is understood that the young are of a yellowish-brown colour, pale or sand-coloured on the under part, and thus it is possible that the last-mentioned one may be this species, at an intermediate age between the brown of the young and the black of the old one. The naked skin of the paws is black and very soft; the callosities are of the same colour; the irides are yellow, a colour which very generally indicates a nocturnal habit in animals possessing it, as any one may observe by comparing the eyes of the fox with those of a dog. This is an animal of considerable size, being two feet long in the head and body, and two feet and a half in the tail, and standing fifteen inches at the shoulder, and eighteen at the crupper.

Nestor Monkey (S. nestor). This has not, we believe, been found anywhere in the living state, at least so as to be recorded, though a specimen is in the museum of the Zoological Society. Its perfect analogy to the others leaves little doubt that it belongs to the oriental Archipelago, the grand home of this division of the monkeys; and from its small size, and broken colours, it is not impossible that it may be one of those already mentioned in an early stage of its existence. The following is the description of it, as given in the report of the society's proceedings:—"Length of the body and head sixteen inches, of the tail twenty. The prevailing colour is a deep grey with a slight tinge of brown, becoming paler on the back of the neck and on the head, where the fuscous tinge is much more marked. On the loins the deep grey passes into a pure light grey, which is continued on the hinder part of the thighs and along the tail; the tail becomes gradually light in colour, and is for several inches at the tip all white. In passing down the limbs the prevailing grey becomes gradually darker, the colour of the hands being nearly black. The under parts are somewhat lighter than the upper, particularly about the throat. Passing upwards from the throat, the colour becomes much lighter, owing to a great proportion of the lower part of the hairs being exposed. Hence the lips, the chin, and the whiskers, are nearly pure white, the tips of the latter, which are prolonged backwards, being alone grey. Over the eyes is the ridge of stiff black hairs which is usually met with in the *Semnopithecus*. The hairs are of moderate length, measuring about an inch and a half. The moderate length of the hairs, the somewhat light colour, and especially the white of the lower part of the sides of the face, distinguish the species from *S. leucopræmnus*. It may be assumed to be a native of India; but the dealer of whom it was purchased knew not whence it was obtained.

The *Cochin-china Monkey*, or *Douc (S. nemæus)*. This monkey differs so much from the typical *semnopithecus*, that Illiger formed it into a separate genus, under the name of *Laniopiga*, or hairy buttocks, from the circumstance of its not having naked callosities on those parts of the body like the rest of the section. In its appearance it is perhaps the most singular of the whole monkey race, and seems as if it were clothed with a suit of garments of different materials, something like a fantastically-dressed human being.

The face is purplish, except a line along the under part of the chin, which is white. The naked part of the face extends in nearly straight lines from the chin by the angles of the mouth to a little behind and above the eyes; and without-side this the sides of the head are covered with long sand-coloured hairs, thickly set and reflected backwards, resembling whiskers of vast size. Across the forehead there is a chaplet of black, and the fingers and thumbs, which are covered with hair down to the nails, are of the same colour. There is a brownish gorget on the upper part of the breast, extending back nearly to the ridge of the neck. The body and arms, as far as the elbow joints, is grey, darker on the shoulders, and deficient of hair on the belly. This grey portion extends forwards to the black chaplet on the forehead, and it terminates a little above the insertion of the tail, so as to have something of the appearance of a close round jacket with short sleeves. The fore arms and hands down to the division of the fingers are yellowish white, with a sort of rosy or reddish brown in it, not unlike the colour of the flesh of some of the eastern nations of the human race. The lower part of the rump and the tail are nearly the same colour, but more inclining to pale reddish bay. The thighs are grey, but with a purplish or brownish tinge, forming a contrast with the grey on the body, and consisting of longer and more shaggy hairs. This colour barely reaches the knee-joints, and does not join the grey on the back, the light bay red there extending nearly from flank to flank, and the posterior part of the colour on the thighs terminating in a darker margin, as if it were a fold. Thus the colouring of this part of the animal has a considerable resemblance to a pair of breeches, somewhat scanty in longitude at both ends, and not girded up in the most seemly guise at their sacral termination. The legs are purple brown, paler in the tint, and not containing so much grey as the thighs; they thus have a slight resemblance to a pair of stockings. The divided part of the hind feet is black, which finishes the fancied resemblance to a human costume, by making the animal appear to be slipshod. Some idea of this animal, in its form, if not in the peculiarities of its colouring, may be formed from the following cut.

We believe that this species was first known in Europe from an imperfect specimen brought from Cochin-China, which was the cause of its being named after that country. It occurs, however, in the islands

and numerous specimens being forwarded to Europe by M. Diard, more satisfactory accounts of it were obtained. From these it appears that the animal actually has callosities on the buttocks, though to cursory observation these are concealed by the long hair on the parts. Indeed it does not appear that there is any good reason for making a separate genus, or even subgenus, of this animal, though it is unquestionably a well-marked and very peculiar species. Its height when standing on the tarsi is about two feet; and the tail, which is rather slender, is about the same length as the body and head. From the accounts it should seem that, though this species keeps much in the covers of those natural forests which overrun every part, not immediately in cultivation, of the lands which it inhabits, it is far from being rare in these, while its geographical distribution is more extended than that of many others of the oriental monkeys. If it could be introduced in the living state, and kept alive, it would be the best show monkey of all the race; because it is a monkey ready dressed, and would not require that fantastic apparel in which these animals are sometimes tricked out, in order the more forcibly to attract the vulgar gaze.

The Proboscis Monkey or Kahall (S. nasica). From the extraordinary production of the nose, standing out from the line of the face like a great beak, this animal has been made the type of a genus under the name of *Nasals*; but it is doubtful whether the structure of the nose, curious as it is, warrants the separation of it from the semnopithecii, with which it agrees in its more active and important organisation. The face of this monkey bears a considerable resemblance, in all respects except colour, to that which exhibitors give to the standing hero of street pantomime, the venerable and far-famed Punch. Whether the monkey or the mime has the more grotesque visage is a point not worth determining; but the monkey certainly has a supply of nose worthy of the immortal pen of Slaukenbergius himself, and doubtless has been at the promontory of noses. When the animal stands at its greatest height, elevated on the hind feet, it does not exceed three feet, and yet the nose stands full four inches out from the line of the face, and the chin also is pointed. The nostrils are in the under part of this curious proboscis near its extremity, and of an oval form. The face is black, with a bluish tinge, and distinctly marked off by the different colours of the forehead and cheeks; and the yellowish-brown irides of the eyes and large white teeth conspire with the other features and the colour in giving by no means an agreeable aspect to the animal. The upper part of the face is deep red, which extends both over and under the ears, so that only a portion of them appears; and the chin and cheeks have a beard of pale yellowish red, curling upwards on the former, and backwards and outwards on the latter. The general colour of the body is reddish-brown; but it has numerous markings, which, in their general distribution, bear some resemblance to those on the Cochin-China monkey, only the smaller markings are more numerous. The breast and belly are slightly tinged with grey, with a bright bar across the mammæ. The arms to the elbow-joints are bright reddish, with a cross bar of bright colour near the shoulder, resembling the stripes worn by non-commissioned officers of the army. From the elbows to the nails the arms and hands are yellowish-brown, with the naked palms bluish black, the same as the face. There are various

markings of pale colour on the lower part of the back; and a portion of the lower part of the body and the tail are pale yellowish-brown. The hind legs are nearly the same colour as the arms, but the hair on the thighs is shaggy, and has a mixture of blackish-grey among the brown.

Some of the characters of this species are not very well made out; but it is said to make a slight approach to the gibbons or long-armed apes in the length of the arms; and also to the howling monkeys of America in the bone of the tongue and the guttural sac.

Another species, or, more strictly speaking, specimen, with a much shorter proboscis, has been brought from the same country as the long-nosed one; but the probability is that it is the young in a state of partial development. The island of Borneo is understood to be the head-quarters of these very singular monkeys; and we are not aware that any of them have been hitherto found in any other place even of the east. Now Borneo, though the largest of all the eastern islands, is the one with which we have by far the least acquaintance, and what we know of its natural history is mostly at second hand, and not always from authorities upon which we can place dependence, and therefore we must receive with some caution the accounts which are given of its productions. The monkeys under description are described as being gregarious, and as collecting each other together by loud cries resembling the word *kahau*, which is the name given to them in their native land. Their times of general meeting are said to be before sunrise and at sunset, which accords with the colour of their eyes as nocturnal or twilight animals. Their places of rendezvous are the trees near the banks of the rivers and streams, among which they move about with great activity, jumping with ease eighteen or twenty feet from branch to branch, or from tree to tree.

The Gilded Monkey (S. auratus). This species is not known, except from museum specimens. It is about two feet in length, and the tail about as much. The whole fur is of a bright golden red, with the exception of a black spot on each knee; but the belly is almost bare of fur. The anterior fingers have fur down to the second phalanx, and the hind ones to the roots of the nails. Its characters are decidedly those of the order; and it is presumed that some of its manners at least correspond, though nothing is known with certainty about it. It is understood as being a native of the Molucca Islands; but even on this point we have no certain information.

There are several other species, or rather single specimens, described by authors; but, generally speaking, their appearances are not well made out from the mutilated skins which have been brought to Europe, and eagerly purchased by collectors without much inquiry as to where they came from, or what were their habits in their native land. It appears, however, that the whole of the semnopithecii are inhabitants of the south-east of Asia and the adjacent islands, the islands being their head-quarters. From those which we have enumerated it will readily be seen that those oriental islands are completely a monkey's country, and the same may be said of apes properly so called, with the exception of the chimpanzee, which is wholly African, and better adapted for walking than the orangs and gibbons of the oriental woods. There is indeed a regular gradation in these

animals, from the oran to the smallest monkey, though we know too little of their habits and history to enable us to arrange them in the proper order of succession. It has been said that at least one of the species (*S. maura*) has been found in the island of Madagascar; but this seems a mistake, the Madagascar animal being allied to the baboons, or at all events to the macacos, the former of which are chiefly African, and the latter Asiatic animals.

That handed animals, far better adapted for climbing than for any other purpose, should be so abundant in the south-east of Asia, the greater part of them chiefly if not exclusively adapted for vegetable food, is a proof of the vast production of wild fruits in that garden of the globe; and the fact that these animals are not so omnivorous in the structure of their teeth as the handed animals of Africa, agrees with the more uniform fertility of the eastern country.

There is still another division of monkeys of the eastern continent to which the name macaco has been given, which name is understood to be a general one for all kinds of monkeys, at least in some parts of the coast of Guinea. The animals which some describers include in this division are not very clearly defined; and if a perfectly natural classification of the quadrumana could be made, it is not easy to say in what place they ought to be arranged. Some of them partake much of the baboon character; others more resemble the apes, at least some species of ape; and others again more resemble some of the monkeys. They have the teeth of the monkeys; and, like the *semnopithecii*, they have a fifth tubercle to the last molar. They have also cheek-pouches and callosities on the buttocks. Their legs are, however, shorter and proportionally stouter than those of the monkeys, or even the apes; their muzzles are more produced, and their facial angles more acute. When young they are docile and manageable; but when they grow up, the males especially, are ferocious, and their manners partake not a little of the offensiveness of those of the baboons. From their structure, they are of course better walkers than the more typical monkeys, but much less expert in their movements among trees. They are chiefly found in Asia; and some of the species spend a good deal of their time on the ground. We shall mention very briefly one or two of the leading species.

Radiated Monkey (M. radiatus). This is an Indian species, particularly abundant on the coast of Malabar, though it stands the climate of Europe better than many of the others, and breeds freely in confinement. Its principal colour on the upper part is greenish-grey, which is also continued on the upper part of the tail; the under part and insides of the legs are whitish. The length of the body is about a foot and a half, and that of the tail not quite so much. It appears a stouter animal in proportion to its size than the more typical monkeys.

The Chinese-bonnet Monkey (M. Sinicus) has the fur on the upper part bright fawn colour, with the tail slightly brown, and the under part of the body and insides of the legs whitish. The naked parts of the feet are black, and there is a streak of the same colour on the lower lip, but the face is flesh-coloured. The produced hair on the upper part of the head, on account of which it gets its trivial name of Chinese bonnet, gives it rather an odd appearance. This tuft is divided on the top of the head, and turned towards each side, reaching the ears; and there is a black

line a little over each eye, something in the position of an eyebrow, but placed higher on the forehead. The hair over the body of this species is particoloured, the base of each hair being grey, and the remaining part marked with alternate rings of black and yellow, only the yellow predominates. It is a native of the East, being found on the main land of India, and also in some of the islands.

The hair-tipped Monkey (M. cynomolgus) is generally understood as being an African, from which country it is very often brought to Europe. This is larger in size than either of the Asiatic species, and approaches more to the structure of the baboons, though it still has the tail nearly as long as the body. The full-grown male is nearly two feet and a half in length, and the tail is little less. It is thus larger than any of the monkeys properly so called; and it is also much more clumsy in its structure, especially in the structure of the fore legs. It has a large head, flattened on the under part, but the muzzle is short and blunt. The nose is flat, and there is a remarkable elevation or ridge and crest which projects over the eyebrows. The fingers are united by membranes as far as the second phalanx, so that this species has not equal command of the fingers with some of the others. In a state of nature there is not much known of its manners, but in confinement it is much less lively and disposed to climb than the lighter and longer-limbed monkeys. It walks readily on all fours, and rests itself by squatting on the callosities. The mouth and hands are indiscriminately used in the operation of feeding, and the cheek-pouches are always filled before the process of swallowing is begun. This last is, indeed, a habit with most of the quadrumana which have cheek-pouches. The position of repose is either on the side, or resting on the callosities with the head bent forward between the knees. The female is considerably smaller than the male, and more handsome in form, if handsomeness can be predicated of creatures which are unshapely in their forms and repulsive in their manners. The head is considerably smaller than that of the male, and, though the crest is not so projecting, it equally covers the eyes. The hair on the top of the head is directed from both sides toward the mesial line, where the two united stand up forming a crest, which has procured this female the name of the *agret monkey*. The face is bordered with long and straight grey hairs, which give it a curious appearance. The canine teeth of the female of this species, and indeed of all the species of this imperfectly understood division, are very small, not projecting beyond the incisors; and the female has not the same vicious disposition as the male. It appears, however, that she is wanting in an instinct for which many of the monkeys are remarkable, and which has been so long known as to have been made the foundation of some ancient fables. We mean the instinct of attachment to her offspring. Very many of the handed animals are remarkable for the most solicitous tenderness in this respect, and it displays itself in so many little attentions and endearments to the young one by its mother, that it goes a good way to redeem the other and more offensive habits of the animals. But the female of this species, at least, when in a state of confinement, pays little or no attention to her offspring. A pair which were kept in the French menagerie produced one young one in 1817, and another in 1818, and on both occasions the mother neglected them, and

they soon perished. No conclusion with regard to the conduct of the animals in a state of nature can, however, be drawn from this, at least with certainty, for confinement alters the natural dispositions of animals, though it is natural to suppose that the attachment of the mother to her young is the last affection that would be changed by this means.

This African species makes a much nearer approach to the baboons than any of the Asiatic ones do ; and though there are still differences, both in appearance and in manners, it might perhaps, with as much propriety, be classed with the baboons as with the monkeys. After it, the next African link, leading to the more typical and ferocious baboons, is the pig-tailed baboon, of which some notice will be found under the title *BABOON*, in its place in the alphabet.

With the present species, therefore, we close our brief notice of the monkeys of the eastern continent. Altogether they are a numerous, a noisy, and a mischievous race, though the singularity of their forms, their great strength in proportion to their size, and their lively motions, will always render them animals to which a certain degree of interest attaches. To man they may be said to be of little or no use other than the mere gratification of curiosity ; but, though to our feelings there is something repulsive in the idea of eating a monkey, from its imagined resemblance to a dwarf of the human race, it is highly probable that most, if not all of them, would make wholesome food ; and they are so numerous that vast numbers of them could easily be procured for this purpose. Those vast numbers bespeak a corresponding extent of use in the economy of wild nature ; but what that use is, is not so easily determined, the more so that the economy of the forests which they inhabit is but imperfectly known, and cannot be studied with safety, as a tropical forest is always unhealthy in proportion to its closeness, and the vigour of its vegetation.

II. MONKEYS OF AMERICA.—The monkeys of the western continent, which differ much more from all those of the east than the Asiatic and the African differ from each other. In America there are neither apes nor baboons, nor any animals resembling them ; but the monkeys are exceedingly numerous in the extensive forests of tropical America, and they are equally remarkable for their structure and their manners. Some of the handed animals of the east are noisy enough, and the voices of the whole order are screaming and disagreeable ; but the eastern ones are nothing to some of the western in this respect, for the latter really make the woods dismal with their howlings, for the performance of which they have a peculiar organisation, which we shall afterwards notice. Many of the eastern animals are remarkable for the quickness of their motions, and their dexterity in springing to the branches of trees, and so from branch to branch till they traverse the forest faster than any ground animal can follow them, interrupted as it is by the undergrowth below. Their motions are, however, really nothing compared to those of the American species, many of which resemble swift birds in their motions, much more than animals which have no wings. In the general characters upon which animals are classified, there may be said to be a strong resemblance between the handed animals of the two continents ; but in every case it is a similarity without the least approximation to sameness. The American species have the three kinds of teeth

in like manner as those of the eastern continent, but the cheek-teeth are sometimes more numerous. The females have all two pectoral mammae in both continents, and there is much resemblance in the general economy in so far as reproduction is concerned. So also all the four extremities of the Americans are shaped like hands, as is the case with the eastern ones ; but their hands are variously formed, and in some of the species they approach to those of the aie-aie, the galago, and some other tree animals of the east, which, though to a certain extent they are quadrumana, cannot be classed with the typical quadrumana, whether apes, baboons, or monkeys. These last have the claws long and pointed, instead of being flat like nails, as they are in the eastern monkeys, and those of America, which approach most nearly to the eastern ones in their general form. It is to the monkeys of the east, rather than to any other of the divisions of the other, that the American ones have the greatest resemblance. They have long tails, and though they are not prehensile, or capable of laying hold, in all the race, yet many of them possess that species of action in so high a degree, as to combine the grasping of a hand with a degree of litheness and flexibility not much inferior to the proboscis of the elephant. It is true that none of them are divided at the extremity, or otherwise capable of laying hold, except by coiling round the substance which they seize ; but they do this so readily, so firmly, and in so endless a number of positions, that they are truly wonderful instruments, and there are perhaps not any more wonderful mechanical instruments in the whole animal creation.

As is the case with the handed animals of the eastern continent, those of America are conveniently divided into three great groups. The first of these have been styled *Helopithec*i, which we may translate " tree apes," and, generally speaking, they have the tail prehensile. The second have been termed *Geopithec*i, or " ground apes," which have the tail long, but slightly or not at all prehensile, and they in general have the legs much stouter than the group with prehensile tails, but not so long in proportion. The third group have been called *Arctopithec*i, or " bear apes," because their claws are shaped something like those of the bear. This last group consists of only a single genus, *Ouistiti*, afterwards to be mentioned. Popularly, however, all these groups are called monkeys in this country, and we shall bring the whole of them into this article, because we shall save some room, and thereby be enabled to bring out their characters with more clearness. The three groups have been described under other names than those now mentioned, which are, we believe, those given to them by at least some tribes of the native inhabitants of those countries in which they are found. Those names are *Sapajou*, for the first group ; *Sagouin*, for the second ; and *Ouistiti*, for the third. We shall take them under these names, pointing out the several genera into which the first and second groups have been arranged, and also noticing the leading species in each.

1. SAPAJOUS. It will be borne in mind that these are the true apes or monkeys of America, properly so called, though of course the other groups, being handed animals, are also climbers. The characters of these are as follow : the partition between the nostrils is much thicker than that of the apes of the eastern continent ; and the nostrils opening obliquely

toward the sides, and not downward as in these. There are six grinders in each side of the jaw, both above and below, which is one more than is possessed by any of the handed animals of the east, and consequently they possess four more, or thirty-six in all, while the others have thirty-two, as in man. None of them are furnished with cheek-pouches or with callosities on the buttocks, and all of them have the tails long, very muscular, and prehensile. This last character is the one which more immediately and remarkably distinguishes them from the ground apes, which they resemble in most other respects. In this their distinguishing characteristic there are two sub-divisions or sub-groups of them: one with a tail naked of hairs, and only callous, or partially scaly; and the other having a tail covered with hair to its extremity. On this account the first have been called *Gymnuri*, or naked tails; and the second *Cebus*, which implies that organ is hairy.

The *Gymnuri* have far more power in the tail than the other; and, if we except the kangaroo and the whale, there are no animals in whose economy this instrument is so serviceable. It is true that some lizards, or at all events saurian reptiles, have prehensile tails; and so have some mammalia which are not handed, as, for instance, the little harvest mouse; the beaver, too, makes use of its tail as a rudder, and even sculls with it in swimming, and also converts it into a kind of third hind leg when building; but the uses of all these are far inferior to that of the naked tail in these American monkeys. It is often very long, considerably longer than the body; and from the number of its joints it can command space on every side, and lay hold backwards or forwards, upwards or downwards, to the one side or to the other, with the same precision as if it were a hand, and guided by the sight of an eye. From the direction of the eyes in these animals it is not possible that the prehensile tail can be guided by sight unless in very particular instances; and therefore they have naturally in it the same exquisite sensibility of touch which blind individuals of the human race acquire by long experience and practice. The firmness of the grasp which the animal can take by means of this tail is much greater than one would readily believe, for if it makes a single coil round a branch it is quite sufficient not only to support the mere weight of the animal, but to enable it to swing in such a manner as to gain a fresh hold with the hand. Not only this, for, if the hands miss, the tail is sure to take hold, and therefore, let the wind blow as it may, these animals are never shaken from the trees. The power of motion is in the tail itself, and in every part of it, and the muscular structure in which it resides is truly wonderful. While the animal, in so far as the body is concerned, is in a state of perfect repose, the tail can, with the rapidity of lightning, feel about till it gets a hold, and also try the stability of that hold; and if sufficiently stable, the animal, from the length and elasticity of its legs, can throw itself upward, or indeed in any direction, the coil of the tail being the only fulcrum required. Some of the eastern monkeys are very expert in their motions among trees; but there is no known species of mammalia nearly so well adapted for being a tree animal as these naked-tailed monkeys of America; and we may add that no forests are so well adapted for being the haunts of expert tree animals as those which these singular creatures inhabit.

Those American monkeys with naked tails are usually divided into four distinct genera. One of those we have already described in the article *ATELES*, and therefore our present notice may be restricted to the three that remain, which we shall notice as briefly as possible.

HOWLING MONKEYS (*Myctes*). These animals, which have also been called *Stentor*, from the great loudness of their voices, form a very natural and well-defined genus. Their limbs are of mean length, with five divisions on them all, and the thumb on the fore ones about half the length of the second finger. One of the most remarkable parts of their organisation is the structure of the *os hyoides*, or bone of the tongue, and of the instruments of sound with which the remarkable enlargement of this part is connected. This may be regarded as a sort of enlargement of the larynx, which appears externally like a great swelling or goitre, especially when the animal howls. So large is this, indeed, that it gives a singular appearance to the profile, by throwing the muzzle higher up than what appears to be the centre of the face, an aspect presented by no other race of animals. This singular apparatus is so clearly and so popularly described by Humboldt, in his *Zoological Observations on the Animals of Central America*, that we cannot resist quoting it. "The bony cone of the *os hyoides*," says Humboldt, "measured by water, gave a size equal to four cubic inches; the larynx was slightly attached by muscular fibres, and communicated by a membranous canal. The larynx consisted of six pouches, of ten lines in length, to from three to five in depth. These pouches resemble those of the small whistling monkeys, squirrels, and some birds. They have an opening above on the same side with that of the glottis, by which the air cannot enter without shutting the epiglottis. Above the pouches there are two others, of which the lips or borders are yellowish. These are the pyramidal sacs which enter into the bony case, and are formed by membranous partitions. The air is driven into these sacs, which are from three to four inches long, and terminate in a point, but come in contact with no part of the large hyoid bone opening below. The fifth pouch is found in the opening of the arythenoid cartilage, and is situated between the pyramidal sacs of the same form, but shorter; and the sixth pouch is formed by the bony drum itself, within which the voice acquires the mournful plaintive tone which characterises these animals." Altogether the organisation of the neck and under jaw of this animal is very peculiar, and offers some instances of singular provision for a vast power of voice without the least chance of injuring the essential parts of the animal. In reality, the muzzle of the howling monkeys is rather elongated, and the facial angle small, though the vast production of the howling apparatus renders this not perceptible. The occipital hole, through which the spinal cord passes from the skull to the vertebræ, is situated as far upwards as the orbits of the eyes, and directed backwards, not downwards, by which means the spinal cord is secured from all injury which could arise from the pressure of violent action carried on in front. The lower jaw is very much developed both in its body and its branches, so that their depth is nearly equal to the entire height of the cranium. Between these extended walls the principal modifications of the *os hyoides* are placed. The body of that bone is formed into an osseous case or shell, the walls of which are very thin and elastic.

To this there is a large opening backwards, to the sides of which are articulated four small elongated bones, to which the sacs alluded to by Humboldt are attached. This case is in some of the species about two inches from front to rear, and an inch and a half in the cross diameter; and when the animal howls, the os hyoides is depressed below the lower jaw, deep as its branches are. It is not well ascertained in what manner this singular apparatus, an apparatus so different from that of the organ of voice in most animals, acts; but it is unquestionably an instrument of most melancholy music. The animals which possess it, though the largest of the American monkeys, are still not animals of any considerable size, and yet their voices are louder than the roaring of lions, being distinctly audible at the distance of nearly two miles all round. On account of the loudness and harshness of their tones, a stranger would be very apt to suppose that the forests which they inhabit are thickly tenanted by wild beasts of the most formidable description. But the howling monkeys, though they do wage war on such as dare to invade their pastures, wage war of a different sort from that of the formidable beasts of prey; they assail the traveller with rotten sticks, which they break from the trees, and with other less cleanly substances which they themselves supply; so that, when Swift describes the most offensive practices of the yahoos, one would be apt to suppose that the howling monkeys of the American forests had furnished him with the picture. These animals are exceedingly numerous in many parts of South America. Humboldt estimates their numbers in some parts of the forests as being not less than two thousand to the square league. Numerous as they are, however, their value by no means corresponds, at least in the estimation of Europeans. Part of this may be prejudice, for the Indian tribes hunt them with great avidity, shooting them with arrows envenomed with *wourah* poison, shot from the bow, or blown from the tube, according to circumstances. Some travellers in the woods, and Mr. Waterton among others, speak in favourable terms of the flesh of some of the species; but, as they are not much sought after by the hunters among the colonists, it is probable that this eccentric but delightful traveller may have brought no ordinary share of "Spartan sauce" to his monkey feasts. The skins are in some request both in Brazil and the western countries for covering saddles, or being placed on the backs of mules, to prevent their loads from galling them; but the skins used for this purpose are few as compared with the numbers of the animals. Indeed, it is no easy matter to get hold of them. If they are surprised upon the ground, they instantly betake themselves to the trees, and mount so rapidly and so high, that nothing but gun-shot or arrows will reach them; and then, though they are killed, the chance is that their dead bodies shall remain suspended in the tree; for though gun-shot wounds relax all the joints, and even the features of the boldest warriors, it appears that they do not thus affect the prehensile tails of these monkeys, for they hang suspended to the branches after they are dead.

The females of these, and indeed of all the American monkeys, never have any catamenial discharge, and they bring forth only one young one at a time, which they carry on the back. When the mothers are pressed with danger, some writers say that they abandon their young, while Spix gives them a very

different character. He says that, even though a female is wounded, it will not quit its young until it tumbles to the earth exhausted and dying.

The food of these animals is chiefly vegetable, consisting of fruits and also of succulent leaves. As is the case with the greater number of the handed animals, they prefer those woods which are nearest the banks of the rivers, or the marshy places where the water stagnates. The reason of this is obvious: the trees in those places furnish the most constant supply of food, either in fruits, or in leaves, and they also abound the most in insects. There are several species, the most common and the most conspicuous of which is

The *Red Howling Monkey* (*M. seniculus*). This is the species to which Humboldt alludes, under the name of *Monocolorado*, and it is commonly termed simply the red monkey. One of its most distinguishing characters is the nakedness of the face, upon which there are only some short hairs under the eyes and between the orbits on the mesial line. The body is bright golden yellow in great part, but passes into bright red on the shoulders, the thighs, and toward the insertion of the tail. The beard, which covers the whole enlargement on the under jaw, is bright maroon red, and the rest of the legs and also the top of the head are deep maroon, inclining to purple. The hair on the fore part of the head is shaded so as to lie outwards and backwards; and there is another whirl or centre of the hair at the lower part of the neck, in consequence of which the hair on the hind part of the head turns and meets that on the fore part, forming a transverse crest of a semicircular form. The hair on the cheeks is turned forwards and downwards; those on the outsides of the legs are directed downwards; while those on the insides are directed upwards. The length of the full-grown individual is at least two feet, and the tail is rather more, so that among monkeys this is a large animal. The red howling monkey is a native of the woods of most parts of tropical America, unless those which are dry and near the mountains, and have no monkeys' food at some seasons of the year. They are particularly abundant in the woods of Guiana, behind the European settlements in that part of the world. These animals, and indeed most, if not all, of the genus, are gregarious, and live in large troops, the members of which appear to agree well with each other. There is still some little confusion in the species, and it is probable that there may be in the vast forests several species which have not yet been observed by Europeans.

The *Bear Howling Monkey* (*M. ursinus*). This animal is also known by its colonial name *Araguato*. It has sometimes been confounded with the former; but they appear to be quite distinct, and this one much more of a mountaineer than the other. Humboldt found them in great numbers at an elevation where the temperature was not only moderate, but even severely cold, and they made a very loud howling, especially before rain, so that they might be turned into a sort of rude indicators of the weather. In their deportment they are grave-looking animals. In their general form they bear a considerable resemblance to the red howling monkeys; but, being exposed to higher temperatures, they are more abundantly clothed, the under part of the body, which is nearly naked in the other, being covered with hair in this, and the face being also hairy. The hair is

very long, of a golden red colour, pretty uniform over the body. The young are brown. Notwithstanding these differences, it is possible that this may be a climatal variety of the former, changed in its covering, and dwarfed in its size by the severe cold to which it is subjected. We are not aware that there is any difference in its habits from those of the preceding species.

Golden-tailed Howling Monkey (*M. chrysurus*) has been confounded with the red howling monkey, but it is different, at least in the colouring. The last half of the tail and the upper part of the body, from near the tail to near the shoulders, are very bright golden yellow; the basal half of the tail is very bright maroon, and the rest of the body, the head, and the legs, are very deep maroon, passing into purple in the legs. It is easily distinguished from the red one by the head and limbs being of nearly the same colour, whereas in the other they are of different colours. In the red one, too, the tail and under-part of the body are coloured alike, whereas in this they are different, and the tail consists of two colours strongly contrasted with each other. There is also some difference in the teeth, they being longer than in the others, and very regularly set, and the *zygomatic* arches are larger than any of the rest. Still it is probable that this may be the same species which is called the *aragato*, or probably that name may be applied to more species than one; as, in various places both of the east and the west, it is not unusual to call several monkeys by one common name, in like manner as we apply the general name monkey to all the varieties, whether of the eastern continent or of America.

The Brown Howling Monkey (*M. fuscus*). This is a Brazilian species, of which little is known, and it appears sometimes to have been confounded with the *urane* or bear howler, and at other times with the *Betzebus* species of *ateles*. It is indeed so like the former, that it is not easy to distinguish between them. Its general colour is maroon brown, passing into pure maroon on the middle of the back and the head, and having the tips of the hairs golden yellow.

Red-handed Howling Monkey (*M. rufimanus*) is generally of a black colour, with all the legs and the last half of the tail russet. The face and almost the whole under-part of the body are quite naked of hair. It is understood to be subject to considerable varieties of colour, if indeed that which is described under this name is not merely an accidental variety of some of the others. It is said, taking the varieties of colour into the account, to be very numerous in the dense and damp forests of Brazil, and also in those of the extensive valley of the Amazon.

Black and Yellow Tailed Howling Monkey (*M. fascicaudatus*). This is a well-marked species, at least in so far as colour is concerned. Its general covering is blackish brown, with a yellow stripe along the tail; the face yellowish brown, and very slightly covered with hair. The tail is proportionally shorter than any of the others, not equalling the body in length, while in most of the others it exceeds it. It is found chiefly in the forests in the upper provinces on the river Amazon; but in all probability it occurs in other places.

Black Howling Monkey (*M. niger*). The full-grown male of this species is generally black, only a portion of the tail and the lower part of the face are covered with yellow hairs. The face of this one is altogether

hairy, but the hairs are thin and short. The females and the young differ considerably from the males in their colouring. They have the face, the under part of the body, the flanks, the head and the limbs, with the exception of the feet, straw-coloured. The back is furnished with black hair with yellow points, which make the general tint a yellowish ash colour. This species is found in Brazil, and it differs from most others of the genus in some well-marked particulars. It is considerably smaller, not exceeding a foot and a half from the muzzle to the tail, while most of the others are two feet or more; and the naked or properly prehensile part of the tail does not extend to more than the last third of the length of that organ. The muzzle is straight, as in the golden-tailed species; and the teeth are large and parallel, as in that. Still it is probable that it may only be a coloured variety.

The species of which we have now given the names, and some notices, include the whole of the principal part of the howling monkeys of America, as they are known to European naturalists. They are a curious race in their numbers, their habits, their appearance, their voices, and, in short, every thing about them; and they are perhaps the most characteristic mammalia of those extensive and deep forests in which they reside. Of their manners in a state of nature we know but little, because the exploring of a forest in the rich parts of tropical America is a hopeless task, unless the traveller could, like the sloths, make his way among the upper branches of the trees. During the rainy season all below is either stagnant water of inundation, or quagmire which no foot can pass, covered with withered branches, and divided by natural ditches and pools of water, more offensive to the sense and more injurious to the health than "the reek o' the rotten fens;" while, when the subsoil gets a little finer, so exuberant a vegetation springs up, that the forest is impenetrable, or, when penetrated, it is as dark as midnight. Thus its inhabitants cannot be examined in their strong holds, but merely in those openings which now and then occur, and to which the howling monkeys often resort to bask in the sun. At such times, however, they are very watchful, and, in all probability, some are constantly on the watch; because the instant that a traveller approaches the howl is set up, the whole are instantly on the trees, and begin their cannonade of sticks and other substances, to which we have alluded.

Our next business in regular order would have been to notice the spider monkeys, or the genus *Ateles*, which some naturalists have divided into the two genera of *Ateles*, properly so called, and *Eroides*; the first comprising those in which the thumb is very nearly or altogether wanting, and the second those in which, though the thumb is very short, or even only a tubercle, it can act against the fingers. There is, however, still another genus with the tail prehensile, with the legs very long, as in the spider monkeys, and with the head round, and thumbs on all the extremities, as in the howling monkeys. This is the genus.

LAGOTHRYX.—This genus, which is but a recent addition to the zoology of South America, being first mentioned by Humboldt and Bonpland in their researches in that continent, has received its generic name from the produced hair upon the thorax. The legs are considerably shorter and stouter in proportion than those of the spider monkeys, and thus the ani-

mals are better adapted for walking on the ground. They have four fingers and a thumb on each of the fore feet, the latter capable of acting against the others. Still they are but rudely-formed hands, for the fore finger is so short, that, when the palm is applied to the ground, the foot has very much the resemblance of a paw, and not of a grasping instrument. This paw-like appearance is farther increased by the form of the nails, which, on the fore feet, with the exception of those on the thumbs, are compressed, and slightly resemble claws. The head is rounded, and their fur is much softer to the touch than that of any other of the American monkeys, with the exception, perhaps, of some of the genus *Ateles*. Their facial angle is about fifty degrees, and their ears are very small. Altogether they seem to be animals of soft and quiet disposition, though very little is known of their manners. Humboldt, we believe, saw but one, and that one was in the hut of an Indian in the valley of the Oronoko. It had not, however, been obtained in the forest there, but considerably to the west, on the more dry and elevated grounds, where the forests are not so close. This agrees with the structure of the animal, which is better adapted for walking, and less so for climbing, than that of the species which have the legs longer and more slender. The account given by the Indians is, that this species associate together in large troops, which meet in the openings of the woods, and hold a sort of council, at which the elders of the band stand up on their hind legs and conduct themselves with all the gravity of senators. As is the case among these, however, those monkey assemblies are not uniformly taciturn. They do not howl in the same deep and dismal tones as the howling monkeys, properly so called; but they occasionally set up a violent chattering, something resembling that cheering and counter-cheering which takes place among men in the sound, and very likely in the sense. They are represented as being terrible *gourmands*, or rather *gourmis*, for it is quantity, not quality of food, of which they are said to be so fond. Three species have been named, but it is probable that two of these are one and the same, and possible that all the three may be climatal varieties. The one of these is

Humboldt's Monkey (L. Humboldtii). This is the one found by that enterprising and intelligent traveller, with the Indian of the valley of the Orinoco. It was an animal of considerable size, being about two feet three inches in the head and body, and with the tail rather longer. The head large and round, and having a blunt appearance, from the smallness of the ears and the shortness of the hair. The hair on the upper part of the body is whitish, with black tips, producing a greyish shade. The hair on the breast is much longer than the rest, and of a brownish colour; but that on the head is very short, of the same colour as that on the back, only rather brighter. The face is of a black colour, and naked, only there are short stiff bristles surrounding the mouth. A portion of the tip of the tail is naked, and that organ is very prehensile. So far as we know, this animal has not been found in the eastern part of South America, though in all probability it exists there as well as in the central part, eastward of the Andes.

The Grison Monkey (L. canus). This species is rather smaller than the last mentioned, and it has been found in Brazil. The upper part of the body and the outsides of the legs are greyish olive; the

head, the tail, and all the under part brown, mixed with more or less of ash colour. It is supposed, however, to be subject to considerable varieties of colour, as some specimens, doubtless of the same species, have been met with with the head almost black. Spix, in his splendid work on the animals of Brazil, mentions another species, and also gives a figure of it under the name of the "smoke-coloured monkey" (*Gastromargus infumatus*): *gastromargus* being the generic name applied by Spix to these monkeys, he being the first to discover their great powers in the gastro-nomic way. This one is, however, so like the former in every thing, except being more of a smoke-grey colour, that it is highly probable they are one and the same species, of which, as we have mentioned, other coloured varieties have been observed.

SAPAJOUS PROPER (Cebus). The grand distinguishing character of these from the whole of those formerly mentioned is the tail entirely covered with short and thick-set hairs, though it retains the prehensile property, yet not perhaps in such perfection as where it is naked, and may be regarded as possessing directly the properties of an organ of touch, as well as those of an organ of prehension. This subdivision or genus may be regarded as holding a sort of intermediate place between the tree monkeys and the ground monkeys, the spider-monkeys being taken as the most typical genus of the former, or the ones most exclusively adapted to a woodland life. Most of those who have attempted to classify these singular and interesting, but obscurely-known animals, have put the howling monkeys foremost among the tree ones, as if they were the most typical genus. In respect of size and numbers, and especially of the noise which they make in the world, they unquestionably stand foremost; but these are not sufficient grounds of precedence among monkeys any more than among men; and Cuvier, though he perhaps knew less of the details of the individuals, especially in their colouring and other external appearances, than other naturalists of far less philosophic and generalising minds, was yet faithful to the structure in taking, as typical of the tree monkeys of America, those which are most adroit among the branches, and most helpless upon the ground. Viewing them in this way, we have, in those American monkeys, a series which is probably more complete than in any other animals with which we are acquainted; for the spider-monkeys are the best climbers of which we have any knowledge, and the structural series comes regularly down till the hand makes a close approximation to a digging foot; and the four-handed race merge into or pass over the still-continued series to the rodentia, and these again to the toothless animals, till we come to the armadilloes, clad in armour, and digging deeply in the ground.

This series, taking all the three orders in their succession, and carefully comparing each order and each shade of generic difference with the corresponding differences of haunt and habit, would be an exceedingly interesting subject of natural study; and would probably better reward any one who should bring to it the requisite degree of knowledge and talent than any other that could readily be named.

It would, however, be attended with great labour, and not a little difficulty; and much must be observed before it can be attempted with any great probability of success; but still it is a mine which will reward for many ages those who have the means and the

ability of working it with skill. The reason which makes the natural history of this part of the world in its more characteristic animals, and their appropriate habits and haunts, difficult, is a very obvious one. The forests of South America are not only the most extensive and the most difficult to be explored of any that are to be found on the surface of the earth, but they are at the same time the most permanent in their nature. The high mountains, the vast rivers, and the heavy rains of South America, together with the flooding of the ground by those rains, are sure bulwarks to vegetable and animal life against the invasion of the desert. In many instances, too, those munitions of nature are such as to set all the efforts of man at defiance; and thus there is no chance that this portion of the globe shall ever become forestless. In consequence of this we have the animals there in their habitations as they have been, and as they will be, during a lapse of years of which we know neither the beginning nor the end; and thus they will remain a permanent subject for naturalists of successive ages; so that, from the time that the language of natural history became the language of truth grounded upon actual observation, the naturalists of every succeeding age may go on to build upon the labours of their predecessors as a sure foundation, the stability of the fabric being beyond question, and the height to which it may be raised beyond even the fondest hopes which we can entertain in the present state of our practical knowledge on the subject. But to return to the sapajous.

As compared with the former species of American monkeys, the sapajous are agreeable creatures. They are full of life and intelligence; and, though very active in all their motions, they are mild in their dispositions, very docile, susceptible of education, and can show a good deal of attachment to those who are kind to them. They are accordingly more frequent in Europe than almost any other genus of monkeys. In their native forests they live in numerous bands, and are chiefly met with in the higher branches of the lofty trees; but, notwithstanding their gregarious habit, the males are said to be strictly monogamists, and the pair are very much attached to each other. As is the case with the whole order, their principal food is vegetable—fruits when they can obtain them. But when their vegetable food fails they can become miscellaneous in their feeding, and live upon insects, worms, and mollescous animals. They will also, at least in a state of confinement, eat flesh; but it does not appear that they show the slightest disposition to kill any warm-blooded animal. As is the case with the howling monkeys, they produce but one at a birth. This one is carried on the back of the mother as she moves about; but when she rests she attends and fondles it with much apparent affection. It is sometimes said that these animals will not breed in our climates; but this is not the fact, as has been proved by numerous instances. These monkeys have not generally the disagreeable voices of the howlers, or the offensive chattering of the *Lagothrici*. Their usual sound, when in good temper, and not annoyed, is soft and murmuring, and heard at a very short distance. When, however, their passions of any kind are strongly excited (and animals of so much activity and resource are necessarily very excitable), their cries are harsh, sharp, and loud, and heard at a considerable distance. But even then the sound which they utter

is a sort of yelping or squeaking, and not howling; and their calls to each other are always made in the soft voice.

Some of the sapajous are known by the name of musk-monkeys, and others by that of weeping monkeys, or rather perhaps those names are given to the same ones at different times. They have always a slight musky smell, which is indeed a smell very general among South American animals; but in the season of heat this smell becomes far stronger than at other times. The weeping does not imply that they shed tears; it merely alludes to the sound which they utter when frightened, which sound bears no inconsiderable resemblance to the crying of a child.

The north and east parts of South America are the localities where the sapajous are most abundant, or at all events where they have been most observed. Many species have been enumerated, but it is doubtful whether some or even the greater part of them may not be merely accidental, as their chief distinctions are those of colour. We shall content ourselves with short notices of a few of those which are best established.

The Weeper Monkey (C. appella). This species is well known in Europe, better perhaps than any monkey of this or of any other genus. In so far as beauty can be ascribed to a monkey in its appearance (for all animals are beautiful in their adaptations), this one may be said to be a very pretty little creature, though sober in the colours of its attire. It is only about a foot in length from the nose to the tail, and the tail is rather more than a foot. The upper part is of a pleasing and rather bright brown colour, though it does not always show very well in this country, because, though nobody would feel disposed to ill use a creature which is perhaps the most inoffensive of all its order, and certainly one of the most playful, an animal of tropical climates cannot always be made to feel at home in temperate countries; and, when animals are not in good condition, the falling off tells first in the diminished beauty of the fur. The under part is yellowish, and the upper part of the head, with a line down each side of the face, the tail, and the extremities of the feet, are black. It is, however, subject to very considerable varieties of colour, and is understood to alter, with difference of climate, even in the same individual. With us it is much more healthy, and can stand the weather better than almost any other species of monkey. It is usually brought to Europe from Guiana, which appears to be its head-quarters, and it is found there in considerable troops.

The White-fronted Sapajou (C. albifrons) is about the same size as the weeper monkey last described, but differently coloured; the forehead and a portion round the eyes are pure white, and hence the name that it has received. The general colour of the body is greyish-olive, rather paler on the middle of the back and on the under part, and having a slight yellowish tinge there. Humboldt found this species in great abundance in the forests of the Upper Orinoco and the adjoining parts. Numerous individuals live in the same troop. They are by no means alarmed at the approach of man; and both the Indians and the Europeans, and their descendants, are fond of keeping them in their houses as pets. In their dispositions they are said to be more gentle than even the weeper monkeys, and also more playful. *Ouvapavi* is the name given to this species by

the Indians of the Upper Orinoco, though what this name implies in their language is not correctly known. It is a curious fact that there are very few animals of which the names can, in any language, be so interpreted as to have even as much meaning as to point out any one quality of the animal expressible by a more primitive word. From this it should seem that, in the rude stages of society, animals were among the first subjects which mankind called by conventional names, calculated for bringing the subject before the mind of the hearer when it was absent from his bodily observation. This comes very nearly to the account of Adam's first labour, which was that of naming the beasts; and it is satisfactory to find that, even in so trivial a matter as this, the declaration of Holy Writ is in strict accordance with those conclusions to which we are led by personal observation.

Those Indians are very partial to this little animal, and generally keep it in their houses, and their example is followed by the missionaries, and other persons from Europe, or the European settlements, who take up their abode in that wild and remote part of the country. It seems that the animal is particularly fond of riding; for Humboldt mentions one belonging to the Maypuri Indians, which regularly mounted a pig every morning, and sat quietly on its back during great part of the day, while the pig, apparently quite unannoyed by the burden of its little rider, collected its food in the savannah with perfect unconcern. Another, belonging to a missionary, is described as making a cat a substitute for a charger, and that even this animal did not show much resentment. Whether the old fable, of taking the cat's paw to get the burning chestnuts out of the fire, may have been practised by any of these animals, we cannot say (only it is not unlikely); but certainly these little gentle *sapajous* take great liberties with other domestic animals, and, generally speaking, with the greatest impunity.

The horned Sapajou (C. fatuellus). This species is a little, but only a very little, larger than the two which have been mentioned. Its colour is blackish maroon on the back, brighter maroon on the sides, and bright red on the belly, with the head, the legs, and the tail brownish. It is, however, subject to considerable varieties in the general colouring, no two describers exactly agreeing as to the tint of any one part of it. The fact is, that very many animals, tropical animals especially, appear of different shades of colour according to the different lights in which they are seen, and therefore considerable allowance must be made for those diversities which we meet with in the published descriptions. There is another source of apparent difference in many of the monkeys, and in this one in particular. The skin is generally coloured, and not unfrequently of a bright colour, so that it shines through the hair where that is thin, and imparts a colour which the hair does not possess. The skin of this one is purplish red, and the hair on the under part of the body very thin; hence the apparent brightness of the colour of that part. One of the greatest peculiarities in this species is the direction of the dark hairs on the forehead. These rise from a little above the eyes, and stand up higher than the top of the head, which is round, and appears smooth from the shortness of the hair. Seen in front, those hairs of the forehead are parted in the middle, and end in two stiff and pointed tufts, to which the

name of horns has been absurdly given, though "tufted *sapajou*" would have been a far more appropriate name. Seen in profile, the aspect of those produced hairs of the forehead is very different; and, in this situation, the animal altogether bears some slight resemblance to a mailed warrior, with the visor of his helmet up; and the resemblance would be nearly complete, if the naked ear of the animal did not make its appearance. From the angles of the erected hairs on the forehead, the hair on the cheeks turns downwards, and then forwards on the chin, but with an intermediate white patch, bordered by a black one on the side of the cheek. The black might pass for a whisker, and the white for a cowl under the helmet, while the erected part shows as if it could be turned down, and exactly cover and protect the face. All these resemblances are of course purely imaginary, but they belong to that class of imaginary appearances which are well calculated to fix the real appearances in the memory.

The robust Sapajou (C. robustus). This is described as a Brazilian species; but it approaches so nearly to the weeper monkey, that it is probably only an accidental variety of that, the chief difference being, that it is a little larger and a little brighter in the colouring. *Cebus libidinosus* is another Brazilian species, mentioned by Spix, as indicating an approximation to the baboons in some of the more repulsive habits of these ugly animals. The account was given, however, from an animal in a state of confinement; and it is so contrary to the general conduct of the whole genus, that we must regard the habit as individual, and probably artificial, and not as belonging to, or in any way entitled to become, the name and the discriminating character of a species. The description of this one was given as follows:—The tuft on the head blackish brown; the beard curling in a circle round the face; the back, breast, throat, beard, under side of the tail, and limbs, with exception of the arms and thighs, rusty red; the fore part of the throat deep reddish brown; and the cheeks, chin, and fingers, bright brown.

The large-headed Sapajou (C. marriachus). Few individuals of this species have been met with. Such as have been examined have been obtained from some part of South America, though from what particular part is not known. The forehead is rounded, and the eye-balls prominent; the breast, the belly, the cheeks, the sides of the face, and outsides of the arms, pale yellowish orange, passing into white at the fore part on the face, and at the hind part on the arms; the head black on the upper part, and whitish on the sides, with a black band down each side of the face, showing some white between it and the naked part; the legs on the outside, and also the tail, are black; the insides of the legs reddish, but produced more by the colour of the skin than by that of the covering, which is very scanty in these parts. Though the country of this species is not perfectly ascertained, there is little doubt that it is a distinct species, because several have been found agreeing so much with each other, and differing so much from any of the other described species, as to leave little doubt that they are distinct.

Golden-footed Sapajou (C. chrysopus). This is a handsome species, though very little is known concerning it, and it seems to bear a considerable resemblance to the white-fronted one already described, like which it is a western animal, being found in

Columbia. Its covering consists of a number of colours, of which the distribution is similar to that in some of the rest, but the colours themselves are very different.

There are various other species of sapajous, which have been described from their colours, and figured, and recorded in systematic classifications; but, upon careful examination, we are disposed to conclude that the greater number, if not all of them, are accidental varieties, or varieties arising from differences of colour, to which these animals are subject in the different sexes and at different stages of their existence. These differences of colour are very considerable, and in some instances extend as far as absolute albinism, specimens of a perfectly white colour being occasionally met with. In all these, however, there is really no instruction to those who wish to study natural history in a popular manner, or even for useful purposes; because the manners of the sapajous, in all the varieties of their appearance, are so much alike, that, when one is studied, all may be said to be studied; and any one who knows the weeper monkey, which is so very common, can be at no loss to understand all the rest. The sapajous with hairy tails, or the genus *Cebus* of the systematic naturalists, may be regarded as holding the same place in the zoology of America as the monkeys hold in that of the east. Like these, they are by far the most numerous in their locality. There is, however, a remarkable difference between them in the superior gentleness of disposition of the sapajous of America over the monkeys of the other continent, with what genus soever of those monkeys we compare them. The howling and spider monkeys bear a similar resemblance to the climbing apes of the eastern continent; and it is not a little remarkable, that though Africa intervenes between the proper locality of those eastern and western animals, there is nothing in the west approaching so nearly to the chimpanzee and the baboons of Africa as the naked-tailed monkey of America does to the apes of the east. No satisfactory conclusion can, however, in the present state of our knowledge, be drawn from these discrepancies, and the natural history of America must be worked out upon its own data. This is true, not only of the individual races of animals, but of the succession of races; and in the progress from the most dexterous of the handed animals to the most terrestrial of the rodentia, we have to pass through very different gradations in the one continent from those which we have to pass through in the other. The sapajous with the tails entirely hairy may be considered as the last link in those American monkeys which are chiefly, or almost exclusively, tree animals; and we come next to those which have been termed ground monkeys, though of course even they still continue to possess a considerable degree of the climbing character; and indeed, if this were not the case, hands would be given to them in vain, for the chief and proper action of these hands on animals is climbing.

SAGOUINS (*Geopithecus*). These are the ground monkeys of America, and, though various naturalists have confounded them with the hairy-tailed sapajous, they are perfectly distinct. The tail, though often proportionally longer than in the others, is never prehensile. No doubt the animals are capable of moving it, because every lengthened tail is capable of motion and flexure in the different parts; but, though some of the sagouins do often coil the long tail round

other substances, as well as round their own bodies, they never make use of it as a hand, or suspend themselves by it, as is the case with even the hairy-tailed sapajous. These animals have the body long and slender, bearing a very slight resemblance to that of the marten family; their fur is soft, and the tail entirely covered with it; the nails on the fingers are not formed into absolute claws, but they are narrow, rounded upwards in the middle, and rather pointed, something intermediate, in short, between nails properly so called and claws; the eyes of these animals are also larger in proportion than those of the former genera; and the whole structure indicates a lurking animal, having at least a dash of predatory disposition in it. This appears to correspond with the habit in so far as the habit is known; for, as individuals of this species, when in a state of confinement, are very fond of animal substances, including raw flesh among the rest, we very naturally suppose that they are disposed to kill, in a state of nature, any animal they can master. It is not a little remarkable that, in the handed animals of both continents, the strongest species, and those which are most ferocious in their dispositions, should be the most exclusively vegetable in their feeding; and yet such seems to be the case. The handed animals of the east may be said to merge in the loris, and these, notwithstanding the slowness of their motions, are nocturnal animals which prey upon birds. It is highly probable that birds are also, occasionally at least, made the prey of the American ones, for there are not many mammalia in that country which they could master. Those who reflect upon it will easily perceive that it is not a swift animal, which hustles along, but one moving silently and stealthily, which is best adapted for being a nocturnal bird-catcher. Night is the time of repose with by far the greater number of birds; and a wingless animal which is to capture them at this time must come upon them so softly as not to give them notice of its coming, otherwise they would take to the wing and escape. There are indeed other enemies of the tropical birds, which are most in motion during the day, namely, the snake tribes; but they are animals of very considerable resource, and most of them capable of darting upon their prey with equal rapidity and certainty. The sagouins, and animals of similar habits, on the other hand, come by stealth upon their prey. They are not so much found in the lofty forests as the others, though they are still dexterous as tree animals; and during the day they lurk much among the bushes and in the holes of the rocks, while those of the former families are chiefly found in the trees. It is for this reason that they are called *Geopithecus*, or ground apes; and, though the genera into which they are conveniently divided differ considerably, there are common characters which belong to all the divisions. They have the head rounded, and the brain well developed, both of which circumstances are considered as indicating a corresponding share of intelligence in their possessor. The eyes are fitted for nocturnal vision, and during the day the animals remain in their places of concealment. The facial angle is sixty degrees, but though this is large, the approach in appearance to the human face is not so great as in some species which have the facial angle smaller; for the whole have something of a cat-like look. The nostrils are large and open, and directed towards the sides; the ears are also open, and in some species at least they are

S

furnished with an additional concha of fur, resembling the feathered one of the owls, and this no doubt improves their hearing, a sense upon which they necessarily depend a great deal in seeking their nightly food. We can know little upon so nice a point; but it is by no means improbable that those nocturnal preyers, which catch birds and other small game, are led to their game by hearing it breathe. The sagouins have six cheek teeth in each side of both jaws.

These are the general characters; but there are others which belong only to the genera into which these animals have been divided. There are four of those genera: *Callithrix*, or the sagouins properly so called; *Nyctipithecus*, or night apes; *Pithecia*, the Sakis; and *Brachirus*, comprising those American monkeys which have the tails rather short. We shall notice a few of the leading species in each of these.

CALLITHRIX. The type of this genus is the *Saimiri* of Buffon, and the squirrel monkey of common language; but some of the others differ considerably from this typical one, at least in some of their characters. The general characters may be stated as follows:—the head small and round; the muzzle short; facial angle sixty degrees; canines of mean length; the inferior incisives vertical, and not projecting, and coming close up to the canines; the ears long, but unshaped; the tail a little longer than the body, and covered with short hair; the body slender and flexible, so that the animal can make its way easily through small openings. In the squirrel monkey the cranium is remarkably developed; but there are some of the others which have it less so, and these do not exhibit an equal degree of sagacity and resource. The eyes in all the species are of considerable size, and the orbits are completely round. In the squirrel monkey there is a very remarkable development of the external ear; but the others are inferior in this respect, as well as in general intelligence. The colouring of the fur is, generally speaking, finer in these than in any other of the handed animals; and it is worthy of remark, that in this they follow the general law of the mammalia, which is, the more carnivorous the animal is, its fur is the more durable and the more beautifully coloured. It is upon this superior beauty of the covering of these animals that the generic name is founded, for *Callithrix* means "beautiful fur." All the animals of this genus are confined to the tropical parts of America; but, though they are very numerous, their habits in a state of nature are but little known, on account of their spending the day in concealment, and being abroad and active only during the night. We may here again notice, before proceeding to an enumeration of the principal species, a remarkable coincidence between these American animals and those Asiatic ones which appear most nearly to occupy the same place in the economy of nature. They are much more finely coloured, and their fur is also much more glossy than that of diurnal animals which are exposed to the sun in the ordinary economy of their lives. We now proceed to the species.

The Squirrel Monkey (C. Sciurea). This is one of the most finely coloured of all the monkey tribe, and hence it has been called by a number of names. It is the *aurora sapajou* of some writers; and *Saimiri*, which Buffon called it, is understood to be the name given to it by some tribes of the Indians of Guiana. On the banks of the Orinoco Humboldt

found the general name *Titi* applied to it; and there have not been wanting some compilers who have taken advantage of these two names, and given descriptions as of two species or varieties of animals.

The squirrel monkey is of very small size, but remarkably active and very pretty. The length of the body is not more than ten inches, but the tail is thirteen or fourteen. The face is a sort of flesh colour, with the exception of the muzzle, which is dusky. The general colour of the upper part is a sort of olive grey, passing into a paler tint on the under part of the body, and the long hairs, which form a concha round the ears. This colour extends as far as the knee and elbow joints on the extremities, but stops there at a regular section round the limb, and all the rest is bright red, which contrasts finely with the grey on the body. The grey is a colour which can hardly be named, it changes so much with the different ways in which the light is reflected from it; but in all the shades which it shows it is very soft and pleasant to the eye. There is another circumstance, in what may be called the personal appearance of this species, which renders it much more pleasing to look at than any of the rest, and more especially than any of the apes and monkeys of the eastern world. It shows no caricature of the human face; and though, philosophically speaking, there is no harm or ground of offence whatever in this caricature, yet it is, to some extent at least, repulsive to our feelings. Now, though the features of the squirrel monkey are arranged in exactly the same manner as those of the monkeys which do offend us by the caricature, yet there is nothing of the caricature in them. The eyes remind one of those of a cat; and the wide septum between the nostrils, together with the lateral opening of these, so completely animalises the expression, that we admire it as an animal without mixing up with it any comparison of mankind. Besides this, the squirrel monkey is a good-natured and playful animal, and one which was kept for some time in the menagerie at Paris was decidedly a favourite. It seems, however, that the animal is easily excited, and that with it the transition from the expression of joy to that of sorrow is as brief as in a child. When affected by strong passion its eyes fill with tears; and it does not appear that with any ordinary treatment it is ever angry. In a state of nature these animals live in numerous troops, and feed in great part upon insects, though they also eat fruits and small birds. To larger animals they are

perfectly innoxious; and this, together with their beauty and their liveliness, makes them much sought after as pet animals by the European settlers on the coasts of their native country. In the capture of insects they show a wonderful adroitness; and so well are they acquainted with the appearance of this their favourite prey, that Humboldt says they are capital judges of the portraits of insects even in black engravings, and will clutch at them although the same paper contains other representations of nearly the same size as the insects. This is not to be wondered at, because all animals which prey in great part by sight, and especially nocturnal ones, have a strong magnifying power in the eyes, and consequently they can see objects with great distinctness. The squirrel monkeys seize their food indiscriminately with the mouth or with the hand, though most frequently with the latter; and it is not a little remarkable to witness the extreme dexterity with which so small a hand seizes an insect in the act of flying rapidly past, nor is there perhaps any other animal capable of catching flies on the wing so cleverly by means of a single prehensile instrument. There are some coloured varieties of these animals; and in the same individual the colour is understood to deepen with age; it does not appear, however, that there is any thing upon which we should be warranted in founding a specific difference.

The Widow Monkey (C. lugens). This species inhabits nearly the same localities as the former; but it is far more rare, or at all events more rarely seen. The covering is very soft and shining, and uniformly black, except the front of the breast and the anterior hands, which are white. The face is whitish, slightly tinged with blue, and traversed by two deeper lines, which strongly mark the eyes. The produced hair on the top of the head has the black glossed with purple reflections; but the back, the tail, and the hind feet and legs, are entirely black, without any reflection, but by no means destitute of lustre. The manners of an animal belonging to a tribe which dwell in obscurity, and being the most obscure of all that tribe, cannot of course be much known to Europeans. Humboldt, to whom we are indebted for some of the best accounts of the animals of the northern parts of South America, and whose judicious manners recommended him to the most kindly attentions from the Indians, met only with a single living specimen in the hands of those people. They assured him, however, that animals of this species do not, like those of the preceding, or indeed like most of the American monkeys, assemble in troops, and conduct themselves in a sportive manner. They live in pairs, and are of exceedingly sad and melancholy aspect, dozing away their time, and shunning every other animal of the same family. All this sadness and retirement are not, however, indications of simplicity of life; for the widow monkey is perhaps the most carnivorous of all the handed animals of the American continent. It lies in wait, and springs upon its prey like a little tiger; indeed, the bound which it can make, when hungry and excited, by the sight of what will afford it a meal, is more than ten times greater, in proportion to its size, than the spring of the tiger. Birds excite it the most, and therefore we may naturally conclude that they are its chief and favourite food. It is not only more carnivorous than the squirrel monkey, but it is also a more powerful animal. Its body is about a fifth

longer, and all its parts are longer and stronger in nearly the same proportion.

The masked Monkey (C. personatus), is a Brazilian species, and found chiefly in the forests on the banks of the large rivers. It is of larger size than either of those already mentioned, the total length being about two feet and a half, which is almost equally divided between the body and the head and the tail. Its general covering is yellowish grey, but the face, the top of the head, the cheeks, and the tips of the ears, are deep black in the male, and dark brown on the female, and it is from this marking that it has received the name of the masked monkey. The hairs on the back and the limbs, which show the grey colour, are annulated with dark colour and sandy white, and the under part of the body gradually passes into a greyish sand colour. The tail is rather bushy in its covering, and of a reddish yellow; the hind feet, with the exception of the nails, are deep black.

The ruffed Monkey (C. amictus). This also is a Brazilian species, but occurs in the interior of the countries more to the west. It is still larger than the former, being about double the size of the squirrel monkey. The body, the fore-arms, and the legs, are black, mottled with brown; the lower part of the neck and the upper part of the breast white; the feet sandy yellow, and the tail entirely black, and not nearly so woolly as in most of the genus.

Some naturalists are of opinion that the three last mentioned are only coloured varieties of the widow monkey. There appears not to be any structural difference between them which would lead us to infer that there is even the slightest difference in habit; but still the sizes and markings of the colour vary much more than they do in any wild animals which the systematists usually consider as belonging to the same species. We have therefore described them as represented by authors, and we shall do the same with the species that remain, although they also may, in some instances at least, be coloured varieties. This is perhaps the most interesting genus of all the handed animals of America, inasmuch as it appears to form a link between the more typical handed animals and the smaller ones, which are more decidedly predatory, and, as such, referrible to the order *Carnassier*; but, as is very often the case in natural history, the study of these animals is difficult in proportion as it is interesting.

The collared Monkey (C. torquatus). This is understood to be a Brazilian species, but nothing is known of it in the living state. The only account that we have of it is founded upon a single skin in a German collection, and, in so far as colour goes, this skin is different from any of the described species which have been seen alive. The general colour is chestnut brown, passing into yellow on the under part, and the anterior part of the neck is marked with a half collar of white.

The Moloch Monkey (C. Moloch) is a Brazilian species, but exceedingly rare. It is about twice the size of the squirrel monkey. The general colour of the fur is ash; but as the hairs are annulated, a varied and varying colour appears on the back and external parts of the legs. The insides of the legs are bright ash-colour, and the hands and point of the tail pass into pale grey, and indeed, almost into white. The face is brown, and, generally speaking, naked; though there are some straggling rough hairs on the cheeks and chin. The under part of the body and

the insides of the legs upwards are bright reddish yellow, which does not pass into the grey, but contrasts strongly with it at the line of meeting. The hair on the basal part of the tail is very long, that toward the extremity is shorter, and annulated with blackish-brown and sandy-white.

Black-handed Monkey (C. melanochir). This is also a Brazilian species, or, at least, known only to European naturalists as a native of that part of America, and we owe the first account of it to Prince Maximilian of Wied Neu-wied, to whom we are indebted for many particulars respecting the native productions and native inhabitants of that extensive and most interesting portion of the world. It is a large species, measures about three feet in length, of which, however, the tail occupies more than twenty inches. Its fur is long, soft, and woolly; generally speaking, of an ashen-grey on most parts of the body, but really consisting of sand-colour and black or brown, annulated alternately upon the individual hairs. On the middle of the back this passes into a bright maroon-brown, and the tail is whitish, often entirely white, and sometimes with a yellowish tinge. The hands and face are entirely black. This species is much better known than many of the others, being very abundant in many of the Brazilian forests, where it does not inhabit so peaceably as most of the others do, whether in Brazil or elsewhere. Its cry is loud and disagreeable, and numerous bands assemble in the woods about sunrise, and make a loud and unpleasant yelping.

The Mitred Monkey (C. infulatus) is still another Brazilian species, or rather it is one known to us as Brazilian, and not as coming from any other part of South America, though it by no means follows that an animal of tropical America thus described as coming from one locality, may not be equally numerous in other localities. Hence, in countries so extensive, and so nearly alike in their physical character, there is always danger of error when we venture to call a species after any particular locality; because this not only gives an erroneous impression with regard to the individual animal, but limits the labours of those who afterwards seek for it to that locality after which it is named, and this may be the one in which it is least abundant. It is understood, however, that this is a very rare species in Brazil, and it has not been met with anywhere else. Its prevailing colour on the upper part is grey, and on the under part yellowish-red, or reddish-yellow; and the tail is of the colour of the under part toward the base, and black toward the extremity, a large spot of white surrounded with a black border, is situated over the eyes, and forms what is called the mitre. Very little is known of the manners of this species, whether it belong to the more silent and retiring, or to the more noisy; but the probability is that it belongs more to the former, because social animals not only make themselves better known, but are in general more numerous than solitary ones. We shall now proceed to a short enumeration of the night monkeys, or night apes of America, properly so called.

NYCTIPITHECUS.—We have mentioned the preceding genus as being, in a great measure, formed upon the nocturnal model; but, notwithstanding this, they are not absolutely nocturnal animals, but rather crepuscular or twilight ones. We mentioned that the black-faced species assemble and howl at sunrise;

and this appears to be the signal call from the labours of the morning to bring the stragglers in, so that they may betake themselves to their hiding places, and not become a sacrifice to diurnal foes. The present genus are more decidedly nocturnal; and their covering, their appearance, and all circumstances connected with them, are adapted to accord with this habit. Their aspect is soft, and their hair long and curled, or rather waved, and the fur of the head completely concealing the ears, at least in some of the species. This concealment led Illiger to give them the generic name of *Aotus*, which is usually translated "earless," and, as such, it is by no means descriptive of the animals; for they not only have ears, but hear remarkably well, which is indeed a sense upon which nocturnal animals are particularly dependent, and which, consequently, they possess in a very eminent degree, whatever may be the appearance of their external organs of hearing. The word has, however, a different meaning, and one which is descriptive of the animals; for *Aëros* means silk or wool, and by application, that which is silky or woolly; and this is exactly the character of the fur of these animals. But even taking Illiger's generic name in this sense, it is inferior to the other, which is descriptive of the nocturnal habit; whereas a name founded on the mere texture of the covering is of inferior value. The only objection to the literal Greek of night ape is the rugged sound of the word, and on this account F. Cuvier has softened it down to *Nocthorus*. Names, however, are of little consequence, except in so far as they lead us to the right animal, and prevent us from confounding one with another.

The characters of this genus are peculiar and remarkable. In the system of their teeth they agree exactly with the last-mentioned genus. They have the muzzle blunt, the face naked, no cheek pouches, very large eyes, no apparent external ears appearing through the fur; the tail long, the fur woolly, and partially formed into locks; five toes on all the feet; no callosities on the buttocks, and two pectoral mammae on the females. They bear a remarkable resemblance to the lorises in their large eyes, their round head, their nocturnal habit, and their reluctance to move during the day. For a long time there was only one species of the genus known, and the best description of that was given by Humboldt, who had an opportunity of examining it in its native country, and ascertaining its nocturnal habits, so far as the habits of so obscure an animal can be ascertained. More recently, however, other two species have been enumerated; the first, and we believe the only account of which is given by Spix, where they occupy plates eighteen and nineteen of his "New Species of Brazilian Bats and Monkeys," published at Munich in 1820. The manners of these two species are, however, comparatively little known, though, perhaps, they do not differ much from this one, and therefore one may serve for all. We shall consequently make it the chief subject of description, and place it in order before the others.

The Douroucoulis Night Ape (N. trivirgata. Cuvier). This is unquestionably the most singular of all the quadrumanous animals of tropical America, or indeed of any other part of the world, both in the form of its body and in the colour and texture of its covering. Its entire length is about two feet; all its covering on the upper parts of the body is of a peculiar grey colour, the hairs being annulated with black and

white. The under-part, from the chin to the origin of the tail, is orange, a portion of which extends up each side of the neck; the tail is black for the terminal third of its length, and yellowish grey the remaining two-thirds; there is a white eyebrow extending over both eyes, and divided off at each end by a black line extending up upon the forehead, just as far out as the external canthus of the eye; a third dark bar proceeds from the junction of the white eyebrow up the middle of the forehead, or rather of the long hair with which the forehead is beset. These three dark bars which are strongly marked, give a character to the head of the animal, which, if attended to, will effectually prevent its being mistaken for any other. It is from this circumstance that it gets the specific name of *Trivirgata*, the three bars appearing like three rods or "verges," erected coronet-wise on the forehead. This disposition of the line on the forehead is so remarkable, as to have attracted the attention of the missionaries in those parts of the great valley of the Orinoco, where the animals have been observed. They call it "cararayada," though it does not appear to be very eminently deserving of the first part of that name. Though the profile of this species is still the profile of a quadrumanous animal; and though the form of its teeth gives this character to the mouth when open, or when shut, if seen in profile, yet the front view of the face and head altogether, with the exception of no ears, being apparent, bears no inconsiderable resemblance to that of a cat. The eyes are very large, and we believe that the pupils contract to a sort of oval, though certainly not upon a line, as in some other nocturnal animals. The nose is indeed much broader than that of a cat, and it is further from the extremity of the upper lip; the chin, also, from the size and vertical position of the incisive teeth, is larger in proportion than that in the cat, and the mouth, taken laterally, is wider. There is, however, a sort of partial division in the upper lip very much resembling that in the cat; and there are stiff whiskers on the upper lip, which, though they are not so long in proportion as a cat's whiskers, no doubt answer a similar purpose, that of enabling the animal to feel its way in the dark. The importance of those appendages to such nocturnal animals as seek their prey among bushes, is much greater than one would be apt to suppose. They enable the animal to steal upon its prey without giving the least alarm, for though stiff, they are very elastic, so that the least touch against any obstacle bends them; and as this is immediately communicated to the sentient bulbs, they are, perhaps, the most delicate of all organs of touch. It is well known that a common domestic cat is incapable of hunting if its whiskers are destroyed; and there is no other way of accounting for the fact, but on the supposition that, in consequence of the want of the whiskers as organs of touch, the animal runs against objects, and makes so much noise as to alarm its delicate-eared prey. The inner surface of the hands and that of the ears is naked and flesh-coloured; but the face, though equally naked, is smoke-coloured in the general tint. The feet, or hands as they are usually called, do not differ greatly from those of the former genus; but those on the anterior ones are but little extensible, or capable of what may be considered as the proper finger-motion. The claws are a still farther departure from the flat nails of the typical hand than in any of the preceding genera, they are

narrow, pointed at the tips; furrowed on the under sides, provided with trenchant edges, a little crooked, and altogether partake fully as much of the character of absolute weapons, as of mere defences to give firmness to the extremities of grasping fingers. The tail, though not prehensile, is capable of a great deal of motion, and no doubt, assists in guiding the course of the animal very much in the same way as the tail of the cat does. The ears, though concealed externally by the fur of the animal, are remarkably well made out, and the eyes are prominent, and of that yellowish-brown colour which we have described. The nose cannot be said to terminate in a decided muzzle as it does in the last genus; and the septum between the nostrils is much thinner, and the nostrils in themselves more oblong. The hair over the whole body is remarkably soft and silky; and the animal is well calculated for making its way among bushes with the least possible degree of noise.

These animals are ill able to endure either the light or the heat of the day, and therefore they pass that portion of their time in a state of almost complete repose. Their mode of reposing is peculiar, and admirably fitted for preserving the elasticity of the spinal structure, which appears to be most essential to these animals in the performance of their nocturnal labours. When reposing, the tarsi of the hind paws are brought under the belly of the animal, and the fore paws resting also on the tarsi, are placed immediately in front of them, the head being at the same time hung down between the fore legs, to the utmost relaxation of which the joints of the neck will admit. The long tail is not, generally speaking, coiled in any manner, but left lying in easy flexures.

In our common notion of reposing by lying on the side, there is something to which the position of repose in this animal is so very different, that we would be inclined, at first sight, to conclude that it is most uncomfortable. When we come to examine it, however, we soon discover that it is one of the easiest positions which an animal can have, and that there are certain points of mutual support in it, to which we can hardly find any thing equal in any other animal's repose. The four palms form a broad base, and the wrists of the fore ones, and toes of the hind ones, bear against each other. About the middle of the height, the elbow and the knee come in contact, and mutually support each other; while the bones of the arm and thigh form a sort of diagonal strut, reaching from the scapular to the insertion of the tail, which insertion is also a point of support to the base of the animal. The way in which the head declines, presses the elbow joints backwards and the fore feet downwards; and, in short, if we examine carefully the relative positions of the different parts of the animal, and their bearings, we shall find in this singular creature's position of repose one of the most beautiful applications of the principles of statics that is anywhere to be met with.

The diurnal repose is taken in the holes of trees, or any other cavities which it can conveniently reach. It does not dig its own burrow, or form it in the wood; but in the trees of tropical forests there are usually plenty of holes ready made by the various genera of wood-consuming insects. When in confinement, this animal will eat bread, fruits, and milk; and, in a state of nature, it is also partial to succulent fruits and sweet vegetables; though there it is, at

least according to Humboldt, a great destroyer of birds; and it is mainly for the capture of these that it preserves the elasticity of its back by the curve which that assumes when it is reposing. It is not a silent animal, but utters several sounds, the different affections accompanying which are not very clearly understood. Its ordinary cry has been expressed by the syllables *muh-muh*, louder than the size of the animal would lead one to suppose, and resembling a sort of miniature of the nightly cry of the jaguar. The jaguar is the tiger of Europeans and their descendants in that part of America; and, accordingly, the creoles on the Upper Orinoco call the douroucouli, the "tite-tiger." It has also a mewing cry—(e-i-ou), which will be readily perceived to bear some resemblance to the mewing of a cat; and it has also a very disagreeable guttural growl which it utters when irritated, and which describers have endeavoured to express by a repetition of the snarling syllables *quer-quer*. This animal is exceedingly difficult to tame, even in its native country, and the whole of the nocturnal quadrumana of America are so delicate, that they cannot be preserved alive out of their native habitat without the greatest difficulty. As their cries would lead one to suppose, they are snarling and irritable animals; and when they are exasperated, the skin of the throat becomes inflated, and the hair stands on end. Such are a few particulars respecting the best known of this very singular genus of animals; and we must content ourselves with merely mentioning the names of the other two species.

Cat-faced Night Monkey (N. felinus). All the three species may be regarded as being a good deal cat-faced; and we are not aware that this is more so than any of the rest. Its covering is described as being greyish-brown on the upper part and reddish on the under, with the last half of the tail black, and a space round the eyes white. The rays or bars which so distinctly mark the forehead of the other species, do not appear to exist in this or in the following.

Howling Night Monkey (N. vociferans). This is named from its nocturnal din, in which, as we have seen, the species first mentioned also takes no inconsiderable share. The colour of the upper part of this one is more inclining to red than that of the former; and it is uniform over the whole body and head, and only a third, and not a half of the tail toward the point is black; still they may be both differently coloured varieties of one and the same species. Hitherto they have been found in Brazil only; and little has been recorded of them even there.

Pithecia—the Sakis. This genus, like the others, was long blended in the common class of South American quadrumana; and some naturalists have proposed to apply to it the generic name of *Cebus*; but as that name is more appropriately applied to the hairy-tailed sapajous, as marking their chief distinction from the naked-tailed ones, it is rather objectionable. The vulgar name of this genus is fox-tailed monkeys, because the tails are, generally speaking, formed into a sort of brush, with the hair much longer in the middle part than at the root. They are night monkeys as well as the former. They admit of subdivision into two genera, though the chief distinctions of these consist in the length of the tails; the other structures and the habits being very much alike in both. Though called night apes as well as the for-

mer genus, they are much less so in reality, and are to be considered rather as dawn and twilight animals than animals of the darkness of night. In this respect they resemble the common fox, with whom the early morning is the busy time, at least in paying his attentions to the farm-yard, though, where foxes are numerous, they may be heard barking for the greater part of the night, at least in certain states of the weather. It is curious to find a correspondence of habit, at least in so far as time is concerned, between animals of which the tails are the only parts that have any traceable resemblance to each other. The sakis make a much nearer approach in some particulars, especially in the form of their bodies, than they do to the genus placed intermediate between them in the system; but the tails not being prehensile at once distinguishes them from the sapajous; and the produced hair, forming a fox-like brush, equally distinguishes them from the sagouins. They have thirty-six teeth in all, and the incisors of the upper jaw are a little peculiar in their form. They are rounded at their cutting edges, sloped on their external surfaces, and hollowed in their internal, so that they bear some resemblance to little gouddges. The canines have very sharp points; and of the grinders, those which may be called the false ones are formed into points, while the true grinders have blunt crowns, whereby the animals are distinguished from the ouistitis, and pointed out as living more on vegetables, and less upon insect food. Their claws also differ very much from the demi-talons of the ouistitis, which last may be regarded as to some extent prehensile instruments. The external characters are: the head round, the muzzle short, the facial angle nearly sixty degrees, the ears of mean size and bordered, the tail shorter than the body and furnished with long puffy hair, and all the feet with five toes, having short claws a little crooked. The sakis inhabit the very depths of the American forests, and spend the greater part of the day, and always the hot time of it, in repose. They are social, but their communities seldom consist of more than seven or eight individuals. They are great destroyers both of wild bees and of their honey; and it is said that some of the more powerful species follow them to share this description of food, or to take it altogether from the sakis. There are several species which we shall very briefly notice.

Red-bellied Saki (P. rufiventer). This is the fox-tailed monkey, and the night ape of Buffon. It has a round face, and a short muzzle, without any beard; its nostrils are oblique and large, and its eyes very large. It is covered over with very long hair, which is as much as three inches long about the middle part of the tail. Its colour is brown mottled with reddish on the upper part, and passing into red on the belly. The individual hairs are brown at the roots, and annulated with red and brown toward the extremity; the forehead is furnished with a sort of toupee of diverging hairs; the hair on the hands and feet is very short; and that of the face is thin, soft, and fine, and of a tawny colour. This species is very common in the forests of the interior of Guiana.

The Yarle Saki (P. leucocephala) has sometimes been confounded with the former, though the external appearances are different. The head and body are about ten or eleven inches in length, covered with brown fur, very long on the upper part, but much shorter on the under, while that on the head is very short. The forehead, the cheeks, and the lower jaw,

are of a pale yellowish sand colour, from which the animal has received the name of *Leucocephala* or white headed. A small space round the eyes, the point of the nose, and the lips, are the only naked parts of the face, and they are of a brown colour. This species inhabits the forests of Guiana, or rather the brushwood on their margins, and in their openings, where the ground is moderately dry; and its chief employment when active consists in hunting for the nests of wild bees, upon whose honey it feeds with great eagerness.

The Monk Saki (P. monachus) is a native of Brazil, at least it has been found only in that country. It is of rather smaller size than the other; and its fur is mottled in rather a peculiar manner, with large spots of brown and dull white. The hairs in the spots are brown at their origin, and golden near the tips. The hair from the occiput is reflected forwards, forming a sort of cowl over the top of the head, from which circumstance it has received the name of monk. The tail is rather longer than the body, and very thick and long in the hair toward the middle part.

The Yellow-headed Saki (P. ocreocephala) is found in nearly the same country with the white-headed one, and is about the same size, so that it may perhaps be nothing but a coloured variety, as not more than one or two specimens of it have been observed. Its colours are maroon on the upper part, reddish-ash with a trace of yellow on the under; and the hands and feet blackish-brown, with the hair on the front, and that surrounding the face, ochre-yellow.

Red-whiskered Saki (P. rufibarba). This species is also described from a museum specimen, ascertained to have come from the neighbourhood of Surinam. Its body is blackish-brown above, and pale red below; the hair becomes very short toward the extremity of the tail, which gives that organ a peculiarly pointed appearance. There is no light colour upon this species, except a small spot over each eye.

The Miriquina Saki (P. Miriquina). This is a species from a more southerly part of America than those which we have hitherto noticed, and it is also of far larger size. The only notice that we have of it is in D'Azzara's Natural History of Paraguay; but as the descriptions of that author have been always verified where subsequent observation has been practicable, we have no reason to doubt them where this has not been the case. It is described as being two-and-thirty inches long, exclusive of the tail, and capable of being tamed, and docile when in that state. Its chief habitat is described as being in the province of Chocoma to the westward of the river Paraguay. It has a very short tail, but very thickly beset with hair; its head is small and rounded; and its eyes large, with irides of a pale yellowish-brown. The face is naked, except the cheeks, which are lightly covered with white hairs; the ears are very large around it, and covered with short soft hair, and the hair on the body is very long, thick, and woolly. All the upper part of the body is of a pretty uniform greyish-brown, formed by hairs which are annulated with white and blackish-brown; the under part of the body is a very bright cinnamon colour; the tail is black, with the exception of a portion of the under side, which is bright maroon. There is a white spot over each eye, pointed upwards, something in the shape of a little flame; and altogether the markings, as well as the size of the animal, point it out as a well defined species. Those which we have enume-

rated comprise all the species of this genus which are known with any thing like distinctness; and, as we hinted in our enumeration of them, it is by no means improbable that several of those which we have enumerated as distinct ought really to be looked upon as nothing but coloured varieties. We shall now consider the other genus which has sometimes been mixed up with this, but which perhaps deserves in strict propriety to be separated.

BRACHIURUS. This genus does not differ very much from the former in its essential particulars; but there are some few differences which may be marked. Of these, perhaps the most characteristic is the muzzle more produced than in the others, and the short tail. Some of them are also particularly ugly in their forms.

The Devil Monkey or Couris (B. Satanus). This animal was first discovered in Brazil, and in appearance it is unquestionably the most peculiar of the race. Its total length, including that of the tail, which is considerably shorter than the body, though longer than the tails of the rest of the genus, is about two feet nine inches. The colour is nearly uniform sooty-brown, with a light trace of purple in it, and altogether as grim a colour as can well be imagined. Its face is naked, and of a dull brown. Its gape is ample, and its canine teeth very powerful. The hair on the body is rather shaggy, and that on the breast thin; but when the animal sits on its tarsi and its hands, a long beard depending from the whole length of the under-jaw completely covers it. The hands and feet are naked for a considerable way; and from the length of the hair upon the clothed parts, the extreme length and tenderness of the tarsi, the long and skinny hands, and the narrow pointed nails, they seem fit appendages to what fancy pictures of a hag or a harpy. Many well preserved specimens of this curious species have been brought to Europe, but very little is known respecting its manners. Its aspect bespeaks an animal of rather a savage disposition; but appearances of this description are not always to be relied on, though the appearance of large canine teeth very seldom fails. This animal has been obtained from Guiana as well as from Brazil, and it is said to frequent the borders of the deserts rather than the woods; but some caution is requisite in every thing that can be said concerning it.

The Capuchin Monkey (B. chiroptis). This species has also been called the hard-drinking monkey; and in doing this it seems particularly careful not to wet its beard, which it holds to one side while it carries water to the mouth with the other hand. In its dimensions and also in its form it is not unlike the last-mentioned species, but its colours are different; and the hair on the head is turned up in a large tuft upon each temple; the face and forehead are naked; and the beard is of immense length. The colour is brownish-red, the beard darker; the eyes are large, and very deeply set in the head; and the nails on all the fingers are bent, but they are not so on the thumbs.

The Black-headed Monkey or Cacagoa (B. melanocephalus) is a very curious species, and differs greatly from the other two. It is comparatively a small species, and the contrast of its colours is remarkable. In the body it is not more than six inches long, and the tail does not exceed two inches; and it appears as if clothed up to the neck, and down to the wrists and ankles, in a close garment bearing some resemblance to a yellowish and dirty sheep skin. The real colour of this, the principal portion of the body

and limbs is a clear brownish-yellow; but the length of it, and its curling into tufts, give it a mottled appearance. The head is wholly black, with a tinge of purple. The portion covered with hair rather darker than the naked part, and showing the ears with a bold relief. The hair, which is turned forward on the cheeks, is a little grisly at the points, and appears like whiskers just beginning to turn grey; while the deep-set yellow eyes give it a very peculiar appearance. The extremities are long and very slender; and the animal altogether has an expression of feebleness. It is a native of the interior of Guiana, where it is gregarious, living in troops; and, like the rest, it is a crepuscular animal. It is represented as being particularly fond of bananas, guavas, and other sweet fruits; and as it is much more feeble in its body, and mild in its aspect than the other members of the genus, so it is represented as being far more gentle in its disposition and quiet in its manners.

Some other species of the genus *Brachirus* have been mentioned as occurring in the woods behind Demerara, and some of these have been described as very abundant in that part of America. One, the *Jacketed Monkey* (*B. sagulata*), has been mentioned as having a long club-shaped black tail, a black beard, and the upper part of the body ochre-yellow. Other markings, beside these, have been mentioned as occurring in the cases of other individuals; but we are not inclined to set much value on those mere differences of colour as being grounds of any thing of importance in natural history. It is highly probable that there may be many species still in the forests, of which we are utterly ignorant; but much research will be required before their history can be cleared up in a satisfactory manner. We therefore proceed to the last division of the handed animals of America, namely, those which have the fingers or toes armed with strong nails.

ARCTOPITHECI, or handed animals, which have the nails resembling the claws of bears. Animals of this description were formerly classed with the last-mentioned division, which have a slight approximation to the present one in the form of the claws. They have also been often described as a single genus by those who have found enough of peculiarity in them to warrant their separation from the rest. They have acquired various names, of which *jacchus* or *jacko* monkeys, is perhaps one of the most common; but in strict propriety they admit of division into two genera, the *Ouinistia*, properly so called, the (*Jacchus*) and the *Tamarin* (*Midas*).

The leading characters of the whole, taken as one little group of handed animals, are as follows: the head rounded, the face flat; the nostrils lateral; no callosities; the tail not in the least prehensile; only five grinders in each side of each jaw, as the apes and monkeys of the eastern continent have, and not six, like the rest of the American ones. With the exception of the inner toes on the hind feet, which have short and rather flat nails, the nails on all the others are compressed, sharp pointed, considerably crooked, and strong, so as to be capable of serving either for climbing or for catching the prey, as may be necessary. The thumbs or inner toes on the fore feet are so little parted from the others, that this group cannot with strict propriety be termed handed animals. They climb by grasping with the foot, but then that foot approaches the form of the feet of squirrels, and holds on, in part at least, by means of the claws. But while

the inner toe on the fore feet is thus nearly as long as the rest, that of the hind foot is very short, so as to be of little use for any purpose except that of preserving their balance. The hind legs are in all the species larger than the fore legs, a structure which invariably indicates an animal having great dexterity and power of leaping. Their tails are always longer than the body, completely covered with hair, and serving no known purpose save that of regulating their motions or prolonging their leaps. The ears are large, membranous, and nearly naked; the nostrils are placed as in the other American groups; the hair on the body, which generally consists of good colours, well contrasted with each other, is generally long and exceedingly soft. It covers all parts of the body except the head and the feet, upon both of which the hair is very short and close.

They live mostly in trees, as is the case with the more characteristic quadrumana; but they are without the resources of the others, or, at least, most of them, whether of the eastern continent or of the western. They are incapable of using the tail as a fifth hand, in the same manner as the typical tree monkeys of America; and they are also without the resource which the quadrumana of the east derive from the callosities on their buttocks. These callosities are curious appendages. To common observation they seem no better than excrescences, which actually disfigure the animals; but nothing can be more erroneous than any conclusion of this kind respecting them. They are points of support, composed of matter exactly similar to those pads on the feet of hoofless animals, which contribute so much, both to the safety and the stability of the owners; and therefore, though the prehensile tails of the western quadrumana make a more showy appearance, it is not a very easy matter to settle the question as to the real advantage of them and the callosities of the eastern races compared with each other. The prehensile tail is a fifth hand certainly; but then, for stability, if not for motion, the callosities of the others are equivalent to two feet.

The little group under consideration are, as we have said, destitute of both of these supplements to the hands in other tree animals; but they have their compensation in the claws, and the extreme lightness of their bodies, and thus they are enabled very speedily and very safely to find their way to the tops of the most lofty trees. In their action among the branches, in the lightness of their bodies, the length of their tails, and in various other respects, they resemble the squirrels much more than any other group of animals; and both groups are perhaps lighter in proportion to the length of their volume measured to the extremities than any other of the mammalia. Of their manners in the wild forests we know not much, but several individuals have been kept alive in European collections. That their mode of living is different from that of the squirrels there is no doubt; and they appear to be animals of greater observation and resource than these animals, lively as they are. The food of the tame ones consists both of animal and vegetable matter; of the former they prefer insects and very small birds, and of the latter sweet fruits. They were fond of looking at themselves in glasses; and they seemed readily to distinguish between friends and foes, even when only their representations in the glass appeared. Of the appearance of a cat they were very unfond. This might have been expected, because the tree cats of America are, in all probability, the most formidable

enemies they have in their native forests ; but there was another animal of which they were even more afraid, and that was a wasp, from which they endeavoured to conceal their heads with their hands, in a state of the utmost excitement. We must, however, close this general view, and very briefly notice the two genera into which they have been divided. The first genus is,

HAPLÉS, consisting of the *Ouititis*, properly so called. The generic characters are, the head round, the muzzle short, the hind head prominent, tail very long and hairy, the upper incisors in the middle larger than the lateral ones, the lower cutting teeth long and narrow, the upper canines conical, and the lower of small size, and the cheek-teeth beset with sharp-pointed tubercles.

The Striated Monkey, or Common Ouititi. This is by no means a rare animal ; and although peculiar, it is rather pretty, and agrees well with confinement. It is pretty generally known and also liked. It is a very small animal, being only about eight inches long in the body, with eleven inches of a tail appended, and very slender, though the fur makes it appear much thicker than it is in reality. All the upper part of the body is covered with very long hairs, annulated with black at the roots, and yellow, and then black, and alternately white again ; so that while the mixture of colours makes a general tint of greyish olive, the whole of the upper part and the tail, and also the external parts of the hind legs especially, are marked with cross bars of darker and lighter shades, which contrast very pleasingly with each other. Those markings are finest on the tail, where twenty black bands and as many white ones occur. The neck and head, with the exception of the face and ears, are covered with blackish-brown hair, without any markings. The paws are covered with very short hair, which is pale brown in some individuals, and pale grey in others. The inside of the legs and the belly are brown, a little mottled with white ; the face is also brown, with the exception of a large spot above the eyes, and a line on the lips. They are, however, subject to considerable changes of colour. We had almost forgotten to mention one very remarkable trait in their appearance, which is a tuft of brownish hairs, varying in the individuals from very light brown to pure white.

This species, which, though called the striated monkey, has very few characters in common with the typical monkeys, is very common in all the tropical parts of America ; and, considering the temperature of its native haunts, it breeds pretty freely in Europe. The number of young varies, being sometimes only one and at other times as many as three. Some that bred in the French Museum, gave F. Cuvier an opportunity of observing their manners with his usual exactness, and reporting them with his usual fidelity. When the female produced three, she very soon after eat the head of one of them, but the other two began to suck, and her disposition soon became changed to tenderness for them. They were borne indiscriminately on the back or under the belly of the mother, though the last was of course, more strictly speaking, the suckling position. When fatigued with carrying the two young ones, she used to apply to the male for assistance, intimating her necessity for it by a peculiar cry not uttered upon any other occasion ; and when she had recourse to this cry, the male took upon himself the burden of the young. In confine-

ment these little animals are not only very indiscriminate in their eating, but very rapacious. They will contrive to catch gold fishes which are kept in ornamental jars ; and Edwards mentions one that acquired some dexterity in killing and eating small eels.

The tufted Jacchus (H. penicillatus), is a Brazilian species, bearing a considerable resemblance to the common one, but differing in a sufficient number of respects for entitling it to rank as a distinct species. The breast and belly are red and not brown ; the white spot on the front is larger, the cross bars on the back are brighter, and the light-coloured hairs do not spread like a fan over the ear, but form a tuft in front of it, while a margin of produced hairs from the nape stands up behind the ear. The manners of this species are but little known.

The white-headed Jacchus (H. leucocephalus), is another Brazilian species, resembling the former one, but yet with well-marked external characters. It is rather larger than either of the two preceding ones, and has the lower part of the back of a deep black colour. This species has the head and throat entirely white, and the ear tuft black. It is usually found in the copses of the mining districts of Brazil.

The eared Jacchus (H. auritus), still resembles the common one in form and size, but is very different in the markings of the colours. The hairs on the back are only black and russet alternately. The throat, the belly, and the flanks are black ; the feet have short hairs, a mixture of black and grey ; the face and chin are white, and the nape of the head yellowish red. There is a tuft of white hairs in front of each ear, but shorter in proportion than the black hairs on the tufted species. The young have the back more striated than the adults, and they want the yellowish red on the top of the head. This species is also Brazilian.

The white-shouldered Jacchus (H. humeralifer), also Brazilian, smaller than the common one, and perhaps only a variety, but very different in the colours. The arms, the upper part of the back, the neck, and all the under parts of the body, are white ; and so also are the ear-tufts, the hairs of which are very long. The top of the head is dusky, the thighs are brown mottled with white, and the cross bars of the tail are black and white, but very indistinct. The tail is longer in proportion than that of the common species ; and though this, as well as many of the preceding ones, has often been regarded as belonging to that species, and being only coloured varieties, yet the departure in the case of this one is so great, independently altogether of colour, that one would require the evidence of absolute descent before confidently referring them to the same species.

The black-tailed Jacchus (H. melanurus). In this species the tail is entirely black with a brownish tinge, and without any cross bars of alternating colours. The body and legs are generally bright brown, except the under parts and insides of the legs, which are reddish white. The feet are brown, and the size of the animal is nearly the same as that of the common species. Like the others it has hitherto been found chiefly in Brazil.

The Mico (H. argentatus), is still a native of the same countries, or nearly so. It is about the size of the common one, but very differently coloured from any of the rest, being generally of a white colour, with the exception of the tail, which is black. It is possible, however, that it may be a partial albino of

the black-tailed species; and so also may be the other variety with a white tail, which has been described. One of the chief reasons for supposing that this one is an albino is the colour of those places where the skin is naked, that is the face and the feet, which are red, as much as to say that the usual colouring membrane of the skin is wanting. Still this has been described as a species under the name of the mico, or fair monkey, for a long time.

Various other coloured varieties of this genus might be mentioned; but the enumeration of them would be only ringing the changes, which colours extend no further than the single individuals in which they are found, and thus they would only burden the memory without informing the judgment. We shall therefore proceed to the last and concluding genus, of this very numerous group of animals.

MIDAS (*Tamarin*). One of the most common names of this genus is eared jacchus or eared monkey; and it is in consequence of the great production of the ears that the name midas has been applied to them. They are not unfrequently included in the same genus with ouistitis, or jacchus properly so called; but besides the greater size of the ears, there are some other differences which are worthy of notice. They have the lower incisors much more trenchant than those of the preceding genus, placed in a more uniform line, and shorter than the canines. Their tails are also much thicker than those of the other genus, and they are never annulated. Very generally they are furnished with long hair on the head and neck, and sometimes the haunches also have the hair on them a good deal produced. It is not very easy to determine which ought to be considered the typical species of this genus, because the species differ much more from each other than those of the former genus do.

The Pinche (*M. ædipus*). It appears that this species is much more numerous in the northern parts of Colombia, than in the countries farther to the east. It is a small animal (which is indeed the character of the genus), being only about seven inches long in the body, but having at least twelve inches of tail. One of the most remarkable traits in the appearance of the pinche is the very long white hair on the top of the head, which, falling backwards and laterally, forms a complete hood. All the under parts of the body and the insides of the legs are also white. The outsides of the legs, the buttocks, and the basal half of the tail, are bright rusty red; and the terminal half of the tail is black. The back is covered with black hairs having yellowish olive points; and these are so arranged as to produce a transverse barred appearance, but the bars are by no means distinct. The length of the body and head is from seven and a half to eight and a half inches, and that of the tail from eight to twelve.

Common Tamarin (*M. rufimanus*) is the typical species of tamarin. It is generally of a black colour, with the feet of a golden red, and the back faintly cross-barred with yellowish-grey. In the northern parts of South America the common tamarin is very abundant where it is gregarious, and large troops are found together in the forests; the usual length when full-grown is about eight inches in the head and body, and rather more than a foot in the tail.

The Black Tamarin (*M. ursulus*) differs but little from the common one, except in colour. It has the hands black, as well as the other parts of the body,

but the back is slightly cross-barred with red. It is understood to be very common in Para, or the country on the left bank of the Amazon, extending south-ward to the point where Paraguay commences. Specimens have not unfrequently been brought to Europe. They are exceedingly irritable in their dispositions; and snarl and bite if any one attempts to touch them, which is a disposition not possessed by the common tamarin, or indeed by the genus generally; but whether, in a state of nature, they display equal pugnacity has not been ascertained. In all the race indeed, and it may be said in all very small mammalia without exception, there is a certain degree of irritability, and disposition to exercise upon slight occasions such weapons as they possess, which is not found among animals of greater size and strength. This is generally true, not merely of different species, but of different individuals or varieties of the same species, of which the little ones are constantly showing their puny fight, while the large ones scorn to take the field, "nisi dignus vindice nodus."

The Silky Tamarin (*M. rosalia*) is one of prettiest of these animals; and it is the one which is vulgarly denominated the lion monkey, though the same name is also given to another one which has the body, and also the tail, a little more resembling those of a lion than the present one. The hair upon this species is very fine and silky, and that upon the head, the cheeks, the back part of the lower jaw, and the breast, is long, forming a sort of mane which fancy can imagine to resemble the mane of a lion. The colour is pretty uniform, being a very delicate golden yellow when the animal is in good health; but it should seem that this healthy state and beauty of colour are both very intimately connected with the warmth and drought of the animal's native country. It has been brought to Europe, and kept there for some time; but it requires to be protected from the damp with the utmost care; and in spite of all the care which can be bestowed upon it in this respect, the bright yellow very speedily fades off, the colour becomes dull white, and the animal puts on a heavy and languid appearance. This species is understood to be very decidedly a tree animal, and very closely to resemble the squirrels in all its motions.

The Lioncito or Lion Tamarin (*M. leoninus*). This is in some respects the most interesting of all the tamarins, and it is also one of the smallest; indeed, all things considered, perhaps the smallest of the whole monkey race. It is a native of the dry countries on the eastern slopes of the Andes; but it never ascends to such a height as that the place of its habitation is ever temperate. It is about seven inches and a half long in the body, and eight or nine in the tail; and both body and tail are very slender in proportion to their length, at least with the exception of the point where there is a little tuft, still further increasing the lion-like aspect; the tail of this one is covered with shorter hair than that of most of its congeners. The general covering is olive brown, not very unlike the colour of the darker lions. The mane, which is very much produced, is the same colour; and the back is slightly marked with short cross-bars of yellowish-white. The tail is black above and brown on the under part; the feet are altogether deep black; and the claws are also black. The annexed cut will give some idea of the general form.

Humboldt, to whom we owe the best description of this animal, because he visited the interior, and it

is seldom seen on the coast, describes it as one of the smallest, and at the same time the most elegant, of all the monkey race. The Indians of that part of the country where it is to be met with are very partial to

it, and fond of keeping it in their cabins whenever they can procure it. Humboldt, however, saw but two individuals in the course of his travels; and one of these had been carried alive from the western side of the eastmost or innermost Cordillera of Andes. These little animals, when kept in a cage, are continually in motion, like squirrels, and their motions are equally rapid. They are very gay and playful, but remarkably short tempered; and when they are irritated they put on a most formidable appearance, considering their trifling size: their manes bristle up, their throats are distended, their eyes glisten, their teeth are shown, they lash themselves with their tails; and not Bottom himself, in the *Midsummer Nights' Dream*, could play the lion to better perfection than it is played by these small animals. They agree more, however, with Bottom's emended or *piano* lionising than with his original *forte*, which was in danger of frightening the ladies; for "they roar you as it were any sucking turtle." In a word, they are exceedingly interesting little animals, and so familiar in their manners that they breed in confinement; but they are very delicate, so that it would be difficult to preserve them alive for any length of time in cold climates. In the upper valley of the Amazon, and those of its effluents, they are by no means rare; but we are not aware that they have been observed either in Guiana or Brazil. Those which Humboldt saw alive in cages were so constantly in motion that it was scarcely possible to make drawings of them; and therefore the figures which are given in the books are not to be implicitly depended on, more especially those which have passed through the hands of ignorant copyists, and have been got up at a cheap rate more for show than for use.

The White-lipped Tamarin (M. labiatus). This species is very remarkable for its colours. The back and the outsides of the fore arms and thighs are brown, dotted with reddish white; the feet, the head, and the tail, are blackish; the inner surface of the legs, the under part of the body, and the under side of the tail near its origin, are bright reddish; the snout is reddish-yellow; and the lips are surrounded with a border of short white hairs, forming a striking contrast with the dark colour of the surrounding parts. This is a small species, and hitherto it has been found only in Brazil.

The Golden-yellow and Black Tamarin (M. chrysomelas). This species has its colours very strongly marked. Generally speaking, it is black, with the front and the lower side of the tail golden-yellow, and the fore-arms, the knees, the breast, and the sides of the head, maroon-red. It is found in the thick forests of Brazil, and also in all the country to the south of the Amazon. The face and throat are surrounded with very long hairs, generally of a golden-yellow colour, but often with more or less of maroon-red. This species differs considerably from most of the others in the tail, which is not above one-fourth part the length of the body; and the body itself is only between seven and eight inches.

The Golden-buttocked Tamarin (M. chrysopygus). The general covering of this species is also black; but the inner parts of the thighs and the buttocks are golden-yellow; the forehead is yellowish; and there is a long mane of black hairs which descends from the head, neck, and throat, and falls so low down as completely to cover the arms and a considerable portion of the shoulders and back. This species, which is well marked, is larger than some of the rest, being about ten inches and a half in length, with the tail half the length of the body.

Such is a general list of the monkeys in all their leading species and varieties, both in the eastern world and in the western. Taking them individually, they are not animals of a very high degree of interest, and they may be said to be of no value to man in an economical point of view; but they are far more numerous than any other family of tropical mammalia, and therefore highly characteristic of wild nature in those countries to which they belong. The American ones are unquestionably the most singular of the whole, and therefore we have described them with the greatest minuteness.

There is another reason why this should be done: South America is at this moment the portion of the world where natural history is least known to Europeans, because of the jealousy both of the Spaniards and Portuguese, while they held the greater part of it as colonies. Their sway is, however, now at an end; the country is equally open and inviting to inquirers; and there is no doubt that the many enterprising and scientific travellers who are at present engaged in exploring it will make valuable additions to natural knowledge.

MONOCEROS (Lamarck; *Buccinum*, Linnæus). The Linnaean genus *Buccinum* included the *Purpura* of the modern school, and this was separated from them by Lamarck, in consequence of its constantly possessing a thin, conical, somewhat curved tooth-like appendage at the base of the right side of the aperture: we may also add that in some species of this mollusc the spire is more elevated than in others; the exterior surface of the whorls is carinated and angular, smooth, or with small imbricated scales in transverse rows; the aperture internally grooved, and we possess a species from the South Seas, whose right side of the opening near the edge presents one or more rows of small tubercles in addition to the tooth; from the growth of the tooth an internal rib is formed, which generally causes a corresponding groove on the exterior. Lamarck's type of this genus, *M. cingulatum*, possesses some singularities: its columella is not smooth, but irregularly plaited or wrinkled, and the tooth does not extend within the interior of the whorls, as in most of the

other species, but appears affixed only at the edge of the lip. De Blainville has made this genus a subdivision of the genus *Purpura*.

MONOCULUS (Linnaeus) One-eyed. Under this generic name Linnaeus comprised a variety of crustaceous *Entomostraca*, varying very greatly in their structure, composing, in fact, in the modern systems, the order *Branchiopoda* (which see), to which all the Linnaean *Monoculi* belong, with the exception of his largest species, *Monoculus Polyphemus*, or the *Limulus Polyphemus*, Latreille, serving as the type of the sub-order *Xyphosura*, belonging to the *Pacilopoda*, which was the first species in the genus *Monoculus*, according to Linnaeus. Under these circumstances the Linnaean name *Monoculus* has entirely sunk, being neither employed generically nor specifically. The name is, however, so appropriate for some of the species which possess but a single eye, and more especially for the Linnaean *Monoculus pediculus* (*Polyphemus oculus*, Müller, the head of which is distinct, and entirely occupied by a large eye), that we would suggest the propriety of retaining it for the last-named insect, rather than suffer a good old Linnaean name to fall into disuse.

MONODONTA (Lamarck; *Turbo*, *Trochus*, Linnaeus). In constituting this genus of molluscs, Lamarck appears to consider it an intermediate link between the *Trochus* and the *Turbo*, with both of which some of its species had been confounded by Linnaeus; he was in this principally guided by the aperture being rounder and scarcely at all depressed as in the *Trochus*, and from the *Turbo* by a thickened callosity running round the columella, forming a projecting angle at the base of the aperture; we cannot, however, consent to call this a tooth-like appendage, as it is, when best defined, nothing more than a notch occasioned by a continuous sulcated groove running uniformly from the spire to the base. There are, however, other remarkable distinctions which may authorise its being distinguished and classed as a division of the genus *Turbo*, to which we are disposed to assign it; these are the rounded entire aperture, the margin disunited at the upper part, and close by an operculum; in some the margin appears double, or rather it is grooved in its thickness. The animal is also organised precisely similar to that of the *Turbo*; it is phytophagous; some breathe air, but the greater number of aquatic species are marine molluscs. The name of this genus appears to us unhappy, as the characters are not sufficiently strong to warrant its application, and it would have applied more appropriately to the *Monoceros*, which more resembles a tooth than a horn.

MONODORA (Dunal). An ornamental shrub called in Jamaica the American nutmeg. The flowers are polyandrous, and the plant belongs to the natural order *Anonaceae*. Gærtner called this plant *Anona myrsitica*. Generic character: calyx in three parts; petals six, in two series, outer ones acutely lanceolate, interior ones ovate, short and thick; stamens bearing subsessile anthers crowded; style none; stigma sitting; berry large, globular, one-celled, and many seeded. The plant thrives in our stoves, when planted in loam and moor-earth, and is increased by cuttings.

MONOPHORA (Quoy and Gaimard). A species of mollusc arranged by De Blainville as a division of the genus *Salpa*; it possesses no testaceous covering, and its singular structure will be more fully explained under *Salpa*.

MONOPLEUROBRANCHIATA is De Blainville's third order of the second class *Paracephalophora*: it includes the families *Subaphysiaceae*, which contains the genera *Berthella*, *Pleurobranchus*, and *Pleurobranchidium*, *Aphysiaceae*, *Dolabella*, *Bursatella*, *Notarchus*, *Elysia*, *Patelloidea*, *Oombrella*, *Siphonaria*, *Tylodina*, *Akera*, *Bulla*, *Bellerophon*, *Bullea*, *Lobaria*, *Sormotus*, *Gasteroptera*, *Atlas*, each of which will be explained under their respective heads.

MONOTOCA (Dr. R. Brown). A genus of evergreen shrubs, introduced from Australia, and belonging to *Epacrideae*. Generic character: calyx five-cleft; corolla funnel-shaped, with a five-cleft limb, throat beardless; disk surrounding the germen, cup-shaped and lobed; stamens with filaments inserted into the tube of corolla, anthers incumbent, two-valved, and somewhat protruding; style simple, stigma headed; drupe, a one-seeded berry. These are greenhouse plants, and succeed and are increased by the ordinary management.

MONOTREMATA. A small group of marsupial mammalia of New Holland, agreeing with the ground edentata among placental mammalia in some particulars, but being so peculiar in others, that they stand alone in the system as distinct from the other marsupial animals as they are from the placental. The character upon which the name of the group is founded is that of having only a single posterior opening to the body, as in birds. On this account many naturalists were long of opinion that these animals are oviparous; but observation has shown that they are mammalia. There are only two known genera, the *ECHIDNA* and *ORNITHORHYNCHUS*, each forming a separate genus. See these articles, and also the general article **MAMMALIA**, in this work.

MONSONIA (Linnaeus, Jun.). A genus of greenhouse perennials, natives of the Cape of Good Hope. The flowers are monadelphous, and the genus ranges among the *Geraniaceae*. Generic character: calyx of five sepals, mucronate and awned at the top; petals five, large, bitten into teeth; urceolus bearing stamens; anthers oblong; style awl-shaped; stigmas five; urceoli five-seeded; seeds with twisted tails. Propagated by cuttings or from pieces of the root.

MONSTER. Any production of nature which, in the form of its organs, or any of them, deviates from the usual type of its species. The word is not applied to unusual colour, or to a deficiency of the usual number of parts. Thus, for instance, an albino is not accounted a monster; neither is an animal which comes into the world without one or more of its limbs. If, however, there is a part which deviates completely from its type, or one which is doubled, or has a portion of a similar or a different part adhering to it, or growing out of the same structure with it, then it is considered a monster, and the monstrosity is considered as being greater in proportion as the part thus produced is larger and more important.

There is nothing in the name monster, considered in its general meaning, which conveys anything more than that the subject to which the term is applied is calculated, *monstrari*, to show itself, or cause itself to be taken especial notice of; and then it may be with propriety, and it is in fact, applied to a remarkable showing of any kind, whether natural or moral, good or bad.

Natural monsters have attracted a good deal of attention, more especially in the ages of ignorance, and much has been written on their physiology with-

out throwing any great or useful light upon the subject. When we calmly reflect, we can easily see that all such speculations must be vain, as incapable of leading to any satisfactory result. Before we are even in a condition for entering upon the inquiry, why, in certain cases, the animal should deviate from its type, we should be in possession of a satisfactory answer to the previous question, namely, why it should follow that type in the majority of instances to which the monstrous cases form the rare exceptions? and, as we have no means of getting correctly at this cause of the general uniformity of nature's productions, it would be in vain for us to endeavour to settle the physiology in the case of monsters, notwithstanding the superstitious associations which the ignorant are so prone to couple with them. Indeed it is chiefly with the view of pointing out the useless and unsatisfactory nature of such inquiries that we have introduced the article *MONSTRA* even in this brief notice.

Monsters are looked upon by the ignorant very much in the same light as miracles, and, like these, they are deviations from the ordinary course of nature. So far all is well; but there is an association borrowed from the miracle which mixes up with the popular notion of the monstrous production, and which is really of mischievous tendency, as giving a most erroneous turn to the thought. The miracle is always supposed to be the result of some supernatural agency external of the common laws of nature, and in opposition to them; and, such being the case, the real miracle is looked upon as a special and immediate act of the Divinity, for the purpose of accomplishing some end which could not be arrived at by the common laws of nature. Historically we know but one subject to which there was the slightest necessity for the application of miracles, namely, the establishment of those doctrines of Divine Revelation, which, being above the utmost extent of the human powers in their peculiar and mysterious parts, do not admit of the same kind of demonstration as facts or deductions in ordinary philosophy. Miracles of this kind were required for only a very limited time. That time has long since gone by; and every supposed miracle which has been mentioned since has been a mere imposture, and abuse of the credulity of mankind, resorted to for the purpose of accomplishing some end which could not be accomplished by fair and philosophical means.

As the production of a monster is a deviation from the ordinary course of nature as well as a miracle, the one is very apt to be confounded with the other; and weak, though well-meaning persons, are very apt to suppose that the monstrous production is the result of a special interference on the part of the Almighty, as well as the true miracle. If, for instance, one of a family shall have the misfortune to be born with any monstrosity, the vulgar conclusion is, that some sin of the parent is thereby visited upon the child; and, even if it should happen in the case of a domestic animal, there is a tendency to look upon it as the punishment of some transgression committed by the master of that animal.

These are errors which struggle with great stubbornness against all the enlightenment of the present times; and, although unintentional errors, they are very mischievous ones, as tending to lay the axe to the roots both of sound thinking and of correct moral feeling, it becomes every one's duty to assist in the exploding of them.

The previous question, upon which we must remain for ever ignorant, ought to keep us right here. We do not, as has been hinted, know why species are, generally speaking, true to their types; but we do know that artificial treatment can, without breaking down the type so as to render it monstrous, change it to a very great extent. These changes are not, however, produced by simple volition on the part of man; for a man may wish and will long enough before he can change a Shetland pony into a dray horse, or a cart horse to a racer. Means must be employed, and persevered in, proportional to the change which is desired; and, if the means have been properly tried by former experience, they never fail of success. But the deviation from the type of the species as to form is merely a physical result, as well as the change of all the parts without deviation in any one of them; and therefore it must depend on physical causes just as much as they do. Consequently, when we speak of a monster as a deviation from the laws of nature, we speak incorrectly. The truth is, that the deviation is not *from* the law, but *of* the law; and unless there were a specific cause in the individual case, adequate to the production of the monstrosity, the monster would not be produced. It is true that this new law, which produces a result different from the ordinary one, is a law of which we do not possess, and possibly cannot acquire, the knowledge; but, notwithstanding this, we have no more right to say that there is a special interference of the Divinity required to produce the deviation from the type in the one instance, than we have to say that there is a similar interference for the purpose of preserving the type in every case where it is not departed from. Deviation or no deviation, the laws which God has from the beginning established for the world's economy are perfectly adequate to carry on that economy; and true to those laws physical nature works, and every modification of the law, whether it be known to us or not as a cause, is as necessarily followed by a corresponding modification of the result as effect follows cause, and expresses the measure of its nature and efficiency in any other case.

MONTEZUMA (Mocino and Sessi). A genus containing as yet only one highly-ornamental tree, a native of Mexico, belonging to *Bombacæ*. Generic character: calyx hemispherical and truncate, the rim sinuated; petals five, and large; stamens spirally twisted round the style, stigma club-shaped; berry globose, four or five-celled, each with many seeds.

MOON SEED is the *Menispermum Canadense* of Linnaeus, a climbing shrub commonly planted for covering bowers, and increased by dividing the roots.

MOON TREFOIL is the *Medicago arborea* of Linnaeus, an evergreen shrub, a native of Italy, long introduced into our gardens. It is usually kept in greenhouses, but will bear the open air with but a slight protection from frost. Seeds or cuttings.

MORÆA (Linnaeus). A genus of bulbous plants, chiefly natives of the Cape of Good Hope, and belonging to the splendid order *Iridæ*. Generic character: spathe elongated, and somewhat scaled; corolla six-parted, interior petals smallest; stamens opposite the gashes of the pistil, filaments partly united; pistillum in three petal-like divisions; capsule three-celled and many-seeded. These bulbs require the same treatment with other Cape sorts; that is, potted in light sandy loam and leaf mould, kept dry while dormant, but duly supplied with water

when growing. They should be fresh potted every autumn, and when they have made roots they may be removed from the cold frame into the greenhouse to flower. They are increased, like other bulbs, by offsets; or they may be raised from their seeds.

MORDELLIDÆ (Leach). A family of coleopterous insects, belonging to the section *Heteromera*, and sub-section *Trachelidæ*, Latreille, having the body of an elevated and arched form, the head inserted very low, the thorax semicircular, the elytra narrowed towards the tips, or very short, and the abdomen sometimes produced into a point. In the form of the antennæ many of these insects approach the *Pyrochroidæ*; whilst others in the form of the maxillæ, tarsal claws, and parasitical habits, are allied to some of the *Cantharidæ*. They differ from these, however, in the solid consistence of the body, and especially in their great activity. The species are generally of small size, and occasionally variegated in their colours; they frequent flowers, especially those of the whitethorn, in the imago state, and fly and run very quickly. The British genera are *Anaspis*, *Mordella* and *Rhipiphorus*. The first has the wing-covers entire, and the abdomen not pointed; whilst the second differs from the preceding, in having the abdomen terminated in an acute point; the tarsal claws are also here denticulated, and the antennæ filiform and serrated. There are seventeen British species of *Anaspis* and eight of *Mordella*, the type of the latter being the *Mordella aculeata*, Linnæus.

The genus *Rhipiphorus*, Bosc, is distinguished by having the elytra narrowed at the tips, so as not to be able to meet in a straight line down the back, nor to cover the wings; the antennæ of the males are deeply pectinated, and serrated in the females. There is only one British species, *Mordella paradoxa*, Linnæus, a remarkable insect, which resides in the nests of a wasp (*Vespa rufa*), and respecting which Mr. Kirby has given the following notice in the second volume of his Bridgewater Treatise.

"Connected with the subject of parasites is a singular history communicated to me by the Rev. F. W. Hope, one of the most eminent entomologists of the present day. In the month of August, 1824, in the nest of the above mentioned species of wasp, he found more than fifty specimens of a singular little beetle, which may be called the wasp-beetle, long known to frequent wasps' nests. From their being found in cells which were closed by a kind of operculum; he conjectures that they lay their eggs in the grub of the wasp, upon which they doubtless feed subsequent to this; upon opening some of the cells, he was surprised to find, instead of beetles, several specimens of an *Ichneumon* belonging to Jurine's genus *Anomalon*. Upon another examination, some days after this, no more of these last insects appearing, he discovered that they had been pierced in their chrysalis state by a minute species belonging to the family of the *Chalcidians*, of which he found no less than twenty specimens flying about in search of their prey. From the above facts, Mr. Hope remarks, we have a convincing proof, if such were wanted, of a *superintending power* which ordains checks and counter checks to remedy the superfecundity of the insect world. First the wasp, a great destroyer of flies and various other insects, and often a troublesome pest and annoyance to man himself, is prevented from becoming too numerous, amongst other means, by the wasp-beetle; then, lest it should reduce their numbers so as to

interfere with their efficiency, this last is kept in check by the *Anomalon*, which, in its turn, that it may obey the law, 'thus far shalt thou come, and no further,' becomes the prey of another devourer. Mr. Hope observed, and the fact is curious, that the specimens of the wasp-beetle obtained from the female wasps were about one-third larger than the others."

MORINGA (Decandolle). A Malayan tree, of rather an ornamental character, belonging to *Leguminosæ*. In India it is called the horse-radish tree, because the roots are so acrid that they are used instead thereof. It is a stove plant, and may be increased by cuttings.

MORMOLYCE (Hagenbach). A very curious genus of coleopterous beetles from Java, belonging to the family *Carabidæ*, and apparently to the subdivision *Brachinidæ*, having the body flattened and dilated, scarcely exceeding in thickness a sheet of paper; the antennæ are as long as the body; the head very greatly elongated behind the eyes; the sides of the thorax dilated and notched; and the elytra furnished with a broad lateral leaf-like appendage, extending far beyond the extremity of the body, giving the insect much more the appearance of a *Mantis* or *Phasma* than that of a carabideous insect; the legs are long and slender. We know nothing of the habits of this remarkable creature, which is specifically named *M. phyllodes*, from its resemblance to a leaf. The length of our fine specimen is not less than three inches and a half. A good figure is given in the title-page of Mr. Shuckard's Manual of Entomology.

MORSE (*Trichecus*). A very singular genus of mammalia, belonging to Cuvier's tribe of amphibious animals, and one of the largest and most remarkable of that singular tribe. There is only one known species of this genus; but the singularity of its appearance has procured for it a great number of names. It is called "the walrus," "the sea-cow," "the sea-horse," and some other names, but they all refer to one and the same species of animal. It has often (see *MAMMALIA*) been classed with the herbivorous cetaceæ; but in this a double error has been committed, for it is not a cetaceous animal at all; neither is it, generally speaking, herbivorous, if we judge of it from its alimentary system, though it is alleged that it occasionally feeds on the more succulent kinds of sea-weed. The only animals with which it agrees in its general structure are the seals; and, although there are very wide differences between them, some of the most essential points are very much alike in both. The hind legs, for instance, though imperfectly developed, and in great part united with the tail by means of the membranes, still exist, while in the cetacea they are entirely wanting.

When, however, we come to examine the teeth, we find a remarkable difference between the teeth of this animal and those of the seals. The teeth of the seals approximate to those of the carnivora; while in the morse there is an approach toward the elephant, though not sufficiently great to bring the animals within the same class, even in their dentition. The most remarkable character of the mouth of the morse is the immense canine teeth with which the upper jaw is furnished. Those teeth are curved downwards and slightly forwards; they are rounded on their external surfaces, and furrowed on their internal.—They form an article of commerce, as ivory; but their texture is not formed of curves of different

colours intersecting each other, like that of the tusks of the elephant; it is of uniform texture throughout its internal substance. They have neither incisive nor canine teeth in the lower jaw; and that jaw is compressed to give scope for the vast canines of the upper, which descend from the sides of the mouth to the distance of fully two feet, and are thick and strong in proportion. The vast sockets required in the upper jaw for supporting those great teeth swell that part out into a large blunt muzzle; and the nostrils, as if pushed out of the way to make room for the great teeth, are turned upwards. Over the sockets of the canines there are placed two tufts of coarse whalebone looking hairs, having the form of great mustachoes which spread beyond the sides of the head. The central part of the mouth, the only part which the animal can use in feeding, is much compressed laterally; and the lower part of the nose, which divides the mustachios from each other, is also very narrow. The shape of the nose is curious, as the extremity of it consists in two loop-like appendages, having their broad ends uppermost, and each surrounding a nostril. The upper jaw contains two incisors, which are very small, and resemble grinding teeth more than cutting ones; and between these again the young specimens have pointed teeth still smaller, which drop out before they arrive at full maturity. The cheek teeth are four on each side of the upper jaw, which are cylindrical in their sections and obliquely truncated on their crowns. In the adult animal these stand at some distance apart from each other, because in the young there are smaller ones between them which drop out like the small one in front of the canines. In the lower jaw there are only four cheek teeth in each side, which in their forms resemble those in the upper jaw. It does not appear that the canines can be used for conducting the food to the mouth, or preparing it for the stomach; but it is highly probable that they are very efficient against enemies; and the animals also use them as hooks in climbing up those steep rocks and masses of ice, the summits of which they could not otherwise reach. The head is rounded; there are no external ears; and the body is tapered away in the rear, like that of the seals. The anterior extremities are developed to pretty nearly the same extent as those of the seals; and they are used as oars or fins in swimming, and as claspers, and partially as a sort of clumsy feet; but the posterior extremities are so united with the tail that they have very little separate motion. The tail is short, in its developed part; but as the whole body, from the internal cavity backwards, acts a good deal after the fashion of a tail, these animals get through the water with more celerity than their appearance would lead one to suppose. The posterior part of their bodies indeed has but a feeble swimming power compared with that of the whales. It has, however, a little twisting motion of a peculiar kind; because the extremities of the hind feet are capable of being, partially at least, elevated or depressed above the mesial line of the tail; and thus the sort of sculling blade, formed by the three, can act either horizontally or slightly twisted to the one side or to the other. From the high latitudes to which these animals are chiefly confined, the danger of following them near the rocks where the weather is so very inconstant as it is in the high northern latitudes, even during summer, there is much less known of the habits of these animals than could be

desired. We do not even know distinctly upon what they feed. The internal portion of the alimentary system is, as we have said, similar to that of the seals; and the seals are known to feed exclusively upon fish, and not by any chance upon marine vegetables. It is probable that the principal food of the morse is also animal; and yet sea-weed is certainly quoted by almost every describer as forming a portion of its subsistence. It is probable, however, that it may only poke among the sea-weed with its long tusks, which can act like a most efficient two-pronged hoe; and thus it may dislodge from the sea-weed about the rocks those animals upon which it feeds. From the absence of both incisors and canine teeth in the lower jaw, the extreme smallness of the incisors in the upper, and the total unfitness of the canines of that jaw, large and strong as they are, for biting, it is evident that the anterior part of the mouth can serve no purpose, except that of a simply prehensile instrument for laying hold of the food; but the curious cup which the under lip and jaw form when the mouth is opened fit it uncommonly well for such a purpose; and from the shortness of the head, and the strength of both jaws, together with the form of the cheek teeth, there is no doubt that these could crush very easily the hardest covering found on any of those crustacea which inhabit the rocks. We are, however, so little acquainted with the actual feeding of the animal, that any conclusions at which we can arrive concerning it are analogies drawn from its external structure rather than facts which have been observed. The animal is confined to the high latitudes, and we believe to the northern hemisphere, at all events no mention is made of it in the southern. There have been instances of its occurrence in the extreme north and north-western isles of Scotland; but they are exceedingly rare, and occur only in severe winters, when the animal is frozen out, or rather in, for a great part of the north. In former times these animals were taken in considerable numbers upon the shores of the Norwegian seas; but such is not the case now, and any which appear even there must be regarded as rare stragglers. There has been a gradual declining toward the north of all the more polar inhabitants of the European seas, in the course of modern history; but whether this is to be mainly attributed to the extent to which they have been captured by the fishers, or to some natural causes, it is not easy to determine.

There is only one species of morse (*Trichechus rosmarus*) to which, of course, the general observations which we have made apply, and indeed necessarily form a part of its particular description. In the extreme north, as, for example, at Spitzbergen, which may be said to be the extreme limit of land in our seas, it is sometimes found about eighteen feet in length, twelve feet in circumference at the thickest part, and with the tusks about two feet. Specimens of this large size are but rare, however; and sixteen feet long, ten feet girth, and twenty inches length of tusks, is reckoned a large animal. A specimen, which came on shore on the island of Harris in December, 1817, was about ten feet long, and, as the tusks were not above eight inches and a half, it was supposed to be a young one. It was shot while resting on the top of a rock. It is probable that it was more abundant on our shores in ancient times, for Strabo mentions that ivory bits of British manufacture were exported to Rome, and it is probable that the

tusks of this animal supplied the materials, though probably also the tooth of the narwhal—which, though now rare as well as the morse, was perhaps more abundant in former times—may have, in part at least, supplied materials for the same purpose.

The general colour of the morse is brown, pretty much like that of the common seal; and indeed there are many coincidences in the characters of the two animals, though the seal is, generally speaking, the more numerous, the more widely distributed, and the more discursive of the two—ranging over a wide extent of sea, while the morse generally keeps near its northern shores.

Both animals are, however, very similar in their habits. They are social, resorting in great numbers to favourite places of the coast, lying on the rocks or the ice-bergs, basking in the sun, until hunger compels them to resort to the water for a supply of food. The female brings forth her young early in the season, and suckles it in the same manner as the female seal does. As the morse is a much more unwieldy animal than the common seal, or indeed than any of the seals, it is probable that it does not fish in the same bold and dashing style. The seal, though, probably from its more landward form, not so swift a swimmer as the porpoise, is yet able to follow the swift fishes, and seize them in the currents. The morse is also less active on land than the seal, but it is more expert as a bank animal, as its tusks enable it to climb to heights which the seal cannot possibly reach. These differences in the conformation of two animals of the same family, living in the same places, present a good instance of that judicious adaptation in nature which prevents any one animal from coming exactly on the ground of another, but provides, that the one shall take that which, in its kind, or the mode of taking it, the other must leave.

Many accounts have been given of the morses, and also of the mode of capturing them, but we shall content ourselves with a short extract from Zorgdrager. "The seals and morses," says he, "come during the heat of summer into the seas near the Bay of Horisant and that of Klock in troops of eighty, a hundred, and even two hundred, especially the morses, which remain there many days, until hunger forces them back into the main ocean. Many morses are seen towards Spitzberg. On land they are killed with lances. They are hunted for their tusks and fat. Their oil is nearly as much esteemed as that of the whale; their tusks are also very valuable. The interior of these teeth is considered more valuable than ivory, and is of a substance harder and more compact in the larger than in the smaller teeth. A morse will furnish half a ton of oil. When one of these animals is encountered on the ice, or in the water, the hunters strike him with a strong harpoon, made expressly for the purpose, which will often glide harmlessly over his thick and hard skin. When it penetrates, the animal is drawn towards the vessel with a cable, and then killed with a lance peculiarly formed. He is then drawn to the nearest land or flat iceberg. They then flay him, throw away the skin, separate the two tusks from the head, or simply cut the head off, cut out the fat, and carry it to the vessel."

The seals consist of many species, and are scattered over almost all seas, sometimes in numbers which defy all counting; and those which inhabit parts of the world remote from each other, generally have

corresponding differences of appearance. The morses on the other hand, are limited to a single species, and confined to the polar regions of the north. Hence we are led to conclude, that the use of them is very limited, as compared with that of the seals. Nor can we fail in being struck with another remarkable fact which presents itself, with regard to the mammalia of the Arctic Polar Sea. The great black whale of Greenland, which is the whale by way of eminence, though in powers of locomotion it is vastly superior to the morse, is yet confined, not only in its locality, but to very nearly the same locality as that animal.

The morse is the largest animal of its group, and its mouth is armed in a very peculiar manner; and the Greenland whale is also the largest animal of its group, that is of the toothless whales, and it also has the mouth peculiarly armed, by having the baleen or whalebone much more developed and perfect than any of the rest. This is a curious coincidence, and one which is well worthy the attention of inquirers.

MORUS (Linnæus). A genus of deciduous trees and shrubs, natives of Asia and Europe, a majority of which are cultivated. Class and order *Monocotyledonae*, and natural order *Urticaceæ*. The *M. nigra*, common mulberry, is well known. The mild acidity of this fruit is exceedingly grateful, especially to persons labouring under fever. It is slightly laxative, and, like the raspberry and strawberry, is said not to undergo the acetous fermentation in the stomach; and hence it may more safely be eaten by gouty patients than many other fruits which have not the same anti-fermentative properties.

The white mulberry is chiefly cultivated for the value of its leaves, its fruit being insipid and very inferior to that of the common species, the leaves of which are equally good with those of the white, and in some parts of Spain and Persia preferred to them as the food of silk-worms. It is likewise a more hardy tree, having, according to the fable, become callous when it changed the colour of its fruit from white to dark red, on absorbing the blood of Pyramus and Thisbe self-slain beneath its shade.

Mulberry trees are easily propagated by layers, or large truncheons of the branches. The story of a gate-post, made of a mulberry trunk, becoming and now remaining a fruitful tree is well authenticated.

MOTACILLA, the generic name of the wagtails. See **WAGTAIL**.

MOTH. The ordinary English name given to the lepidopterous insects comprising the Linnæan genera *Sphinx* and *Phalaena*, the remaining insects of that order being diurnal, and known by the name of butterflies (*Papilio*, Linnæus). Moths are at once distinguished not only by their being seldom observed on the wing during the day, but also by their antennæ not being terminated by a club, as in the butterflies. There is very great diversity in the structure of these insects, of which a vast number of species are inhabitants of moderate climates. In this country we possess nearly 1800 species, and many more are known on the continent. It is true, that of the exotic species our knowledge is but slight, there being very few entomologists indeed who attempt to make collections of the tropical or extra-European species; the consequence whereof is, that the classification of these insects has been very greatly neglected by most authors, and little beyond the establishing certain great typical forms effected. Indeed, it is perhaps a natural consequence of the peculiarities of our climate

that we possess such an extensive series of these insects. Our vegetation is sufficiently varied and luxuriant to support a great number of species, whilst the great duration of twilight in our latitudes calls for a greater supply of species, which appear only during its continuance, than is probably to be found in tropical climates, where the twilight is but of very short duration. In our country, for instance, the functions of these insects appear to be twofold ; first, as plant-feeders ; and, second, as serving for food to the bats and other nocturnal vertebrata ; but in the tropical climates, where the butterflies so far exceed both in number and size our few diurnal lepidoptera, there exists but little necessity for the former, whilst in the latter respect they are still less needed ; because, as stated in the article BAT, the tropical species of this tribe of animals come abroad by day at all hours, their ravages extending to fruits, flowers, the juices of trees, animal substances of all kinds, and, in short, to everything consumable. Hence we may perhaps look upon the temperate parts of the globe as the metropolis of this tribe of insects, as well as of the *Brachelytra*, &c.

As may be supposed, from the great extent of this tribe of insects, there is very great diversity in their size, structure, habits, colours, &c. From the gigantic *Erebus strix* of South America, which measures very nearly a foot across the wings, and the Death's-head moth, capable of instilling terror into an ignorant and superstitious multitude, down to the pigmy gilded creature which revels upon the parenchyma of a rose-leaf, finding between its upper and lower surfaces room "enough and to spare" for its abode, we have every gradation of size. The structure of many of these insects in the perfect state is very interesting and diversified. In some, formed for rapid and long-continued flight, the body is robust and conical, and the wing-nerves of great strength ; whilst in the feeble *Geometrae*, which flit around the hedge-rows occasionally by day, the whole structure is light ; but it is to the *Alucite* and *Pterophori* that we may best apply the term "as light as a feather," because their wings are slit from the tip almost to the base into distinct fringed pieces, which have all the appearance

Bombyx (Saturnia) Promethea, male.

of separate feathers. In many moths we find the mouth completely obsolete, there being not the least

NAT. HIST.—VOL. III.

vestige of the spiral tongue, which forms so conspicuous a character of the order. But it is in the diversity of the sexes that we often find the greatest variation, the males being generally of smaller size and brighter colours than the females ; their antennæ are also often very beautifully ornamented with lateral branches, so as to resemble a double comb (an example of which may be given in the *Saturnia Promethea*, the early history of which we have given in our article CATERPILLAR), whilst those of the females are comparatively simple ; but a still greater diversity exists between the sexes of certain species, the females of which are completely wingless, and their bodies misshapen ; so that it is impossible, except by direct observation, to suppose that the male and female can belong to one and the same species. This, however, is the case with but very few species ; but in almost every instance the males of these species are furnished with beautifully pectinated antennæ. Of the habits of these insects we can here say but little ; they are so exceedingly various, that they have already formed, and will continue to form, the subjects of various articles wherein the different groups are treated upon in detail. We may, however, here remark, that whilst the majority of the species fly by twilight, or during the night, there are some which delight in the hottest sunshine, as the humming-bird hawk moth, the *Sesia*, &c. Many species delight to hover, during the twilight, over the long-tubed flowers, from which, whilst on the wing, they extract the nectar with their long spiral tongue, whilst others are very sluggish, scarcely showing any animation except during the short period of their coupling. Of course, we need hardly mention that all these moths have proceeded from larvæ hatched from eggs deposited by parent insects ; but it may perhaps be necessary to remind some of our readers, who have paid but little attention to these subjects, that such is the fact. The writer had, for example, much difficulty, a short time ago, in making a non-natural-history reader comprehend that "the moth" had got into his wardrobe. He saw no moths flying about, it was true, but the little woollen cases formed by the caterpillars of this particular group of moths (of which there are many species, *Tinea vestianella*, *pellionella*, *tapetzella*, &c.) were plentiful enough ; but we could scarcely make our friend comprehend how these could possibly be "the moths." And this brings us to speak of the different habits of the larvæ or caterpillars of these insects ; but we have need only to refer to our article CATERPILLAR, where we have given ample details upon this part of the subject, as well as to the articles CHRYSALIS and COCOON, considering it necessary in this place merely to state, that amongst lepidopterous insects, which form cocoons, the far greater, and almost entire number, are moths, a few exceptions only occurring in the butterflies ; and that the form of the chrysalis, owing to its being enclosed in a cocoon, is necessarily conical, and not armed with those angulated points observable in the chrysalides of butterflies, and which would be troublesome to a chrysalis enclosed in a cocoon.

Of the colours of this group of insects, it may be in general said that they are obscure, and but slightly varied, exhibiting none of that splendid appearance which is seen with so much delight in the butterfly ; exceptions, however, occur, as we have stated in the article CATOCALA.

There is a circumstance connected with these

insects which every one must have noticed, namely, their habit of entering lighted apartments during the summer evenings, and flying around the candles until their wings are burnt. We are at a loss how to account for this peculiarity in insects whose ordinary habit it is to avoid the light, and to remain inactive until the twilight has commenced. Is it an extatic kind of bewilderment which compels the creature, even at the risk of its own life, to whirl round a light at the particular period of time when it ought to be upon the wing? It would be a curious experiment to ascertain whether a noctua, for instance, would act thus, if introduced into a darkened room in the middle of the day, into which a light were afterwards to be brought. This may seem an absurd experiment; but we have so much to learn of the economy of insect life, that it might possibly tend to other and more advantageous experiments. This habit of flying towards a light is made use of by collectors of moths, who hang a bull's-eye lantern round their necks, and, with the assistance of a flap-net, are enabled to make very extensive captures during an evening's walk.

For the classification of these insects, and for many other particulars which it is unnecessary here to repeat, we must refer to the articles LEPIDOPTERA, HAWK-MOTH, BOMBYX, GEOMETRIDÆ, &c.

MOTHERWORT is the *Leonurus cardiaca* of Linnæus, a British herbaceous perennial, found on gravelly banks, bearing spikes of labiate flowers.

MOUNTAIN ASH is the *Pyrus aucuparia* of Gærtner, a British ornamental tree, found in moist woods. It is cultivated for the beauty of its form and foliage, and for the splendour of its bunches of scarlet berries, so conspicuous in autumn and winter.

MOUSE. See ARVICOLA for some of the species of this exceedingly numerous and curious group; and RAT, for the rest of them, and the general relations.

MOUTAN is the Chinese name of the *Pæonia suffruticosa*, and applied as a specific name in botanical lists. This is a highly-valued plant in China, as well as in this country, ever since its introduction. There are several varieties of it, and all hardy enough to bear the open air, with slight protection in winter; but they flower much finer under glass. They succeed in any kind of garden soil, and are increased by layers or cuttings. The *Ixora coccinea* is called the *Canton moutan* by the gardeners of that city. The Chinese have many varieties of peony not yet introduced into this country.

MOVING PLANT. This is the *Desmodium gyrans* of Decandolle, and the *Hedysarum movens*, or *gyrans*, of Linnæus. The latter described this plant as "wonderful on account of its singular motion, which is not occasioned by any touch or irritation, or movement in the air, as in *Mimosa*, *Oxalis*, and *Dionæa*; nor is it so evanescent as in *Amorpha*. No sooner (continues he) had the plants raised from seed acquired their ternate leaves, than they began to be in motion in every direction. This movement did not cease during the whole course of their vegetation, nor were they observant of any time, order, or direction; one leaflet frequently revolved, while the other, on the same petiole, remained quiescent; sometimes a few leaflets only were in motion, then almost all of them would be in movement at once; the whole plant was but seldom agitated, and that only during the first year. It continued to move in

the stove during the second year of its growth, and was not at rest even in the winter. The irritability of this *Desmodium* is never so great, even in our best hothouses, as it is said to be in Bengal, and its motions here are seldom so lively as those described by Linnæus; though the two upper and opposite leaflets are often observed to rise and fall alternately, provided the temperature be as high as 70° of Fahrenheit, and the plant be placed in shade. The motion is most evident when the stove is closed, and the air perfectly still. These movements have more the semblance of spontaneity than any others that have been observed in the more perfect plants; for the leaflets, if held quiet between the fingers for a short time, and these movements thus prevented, are said, immediately on their release, to revolve with accelerated speed, as if to make up for the time lost during the forcible interruption."

MUCUNA (Adanson). A genus of tropical climbers belonging to *Leguminosæ*, separated from, and including some plants of, the genera *Dolichos*, *Stizolobium*, and *Carpopogon*. Some of the species are remarkable for their stinging properties. Their seeds are imported under the name of "bull's-eyes," and may be used as beads. The flowers are showy, and the plants easy of cultivation in stoves.

MUGILOIDÆ—the Mullet family. The eleventh of those families into which Cuvier divides the spinous-finned fishes, but which must not be confounded with the surmullets, which are sometimes popularly called mullets, but which belong to the perch family, and have not the labyrinths in the pharynx which characterise that division of fishes to which the mullets belong. The whole of this division of fishes are capable of retaining a portion of water for some time in the pharynx, by means of which they can keep their gills moist for a longer or shorter time, and thus live out of the water. The mullets get the name *Mugil*, because, when out of the water, the escape of the small portion of air which is expelled from the lungs murmurs (*mugit*) as if the fish had voice.

The mullet family consists of three divisions, *Mugil*, *Tetrogonurus*, and *Atherina*, which will, however, be better considered separately; and the mullets themselves, which differ considerably in the several species, shortly noticed in this article by themselves as a little sub-group. Taking them in this point of view, they are pretty distinct, and offer the following characters:—Their body is nearly cylindrical, or about equal in depth and breadth; their scales large; two dorsal fins distinctly apart from each other, with four spinous rays in the first one; the ventral fins abdominal, but placed farther forward than the first dorsal, and only a little behind the pectorals; the middle of the under jaw with a compressed, elevated and angular point, which fits into a corresponding groove in the upper jaw; the teeth small, and six rays in the gills; the head is rather depressed, and covered with large scales; their teeth are often so exceedingly small as hardly to be visible to the naked eye; the bones of the pharynx are very much produced, and give the entrance of the gullet nearly the same form as that of the mouth, so that nothing can enter the stomach but liquids or very small substances; the stomach terminates in a sort of muscular gizzard, bearing some resemblance to the gizzards of birds; the pyloric appendages to the stomach are few, but the intestinal canal is long and of ample diameter. The mullets

are handsome fishes, and highly esteemed. They swim near the surface, ascend the estuaries of rivers, and are remarkable for the extensive leaps which they can take out of the water. The species are rather numerous, and there is some confusion in the foreign ones; we shall therefore confine our notices to those species which are found at one part or other of the European shores.

THE GREY MULLET (*Mugil capito*). This is by much the most common of the British species, though it is one respecting which there have been mistakes. It appears, from the *Fauna Italica*, now publishing by the Prince of Musignano, that there are five species of grey mullet found in the Mediterranean, while there are not so many in our seas. *M. cephalus* is one of the species found in the Mediterranean, and not hitherto at least, in the British seas, though *M. capito* is not only found in those seas, but as far to the north as the coast of Norway, and in the Baltic. By some means or other, the trivial name *Cephalus* was for a long time applied indiscriminately to all the grey mullets of Europe; and thus it was made to appear that a fish, which is in reality confined to the warmer seas, is generally distributed. Mr. Yarrell, in his excellent work on British Fishes, thus clearly points out the difference of these two species:—“*Mugil cephalus* is distinguished by having its eyes partly covered with a semi-transparent membrane adhering to the anterior and posterior part of the orbit, and also by a large elongated triangular scale pointing backwards, placed just over the origin of the pectoral fin on each side. A dried specimen of this fish from the Mediterranean, now before me, exhibits both these peculiarities, which *M. capito* does not possess. The appearance of the pectoral fin, and the superposed triangular scale of *M. cephalus*, supply the means of comparison with our own grey mullet, in which the pectoral fin scale is short and blunt.”
